Abstract:
Much analysis in macroeconomics empirically addresses economy-wide incentives behind consumer/investment choices by using insights from the way a single representative household would behave. Heterogeneity at the micro level can jeopardize attempts to back up the representative consumer construct with microfoundations. One complex aspect of micro-level heterogeneity is household size, as individuals living in multi-member households have the potential to share goods within the household, benefiting from household-size economies. Theoretically, we show that validating the role of a representative consumer would require that the way individuals benefit from intra-household sharing is strictly aligned across the rich and the poor: once expenditures for subsistence needs are subtracted from disposable household income, household-size economies the remainder (discretionary) household incomes entail must be the same across the rich and the poor. We have designed a survey method that allows the testing of this stringent property of intra-household sharing and find that it holds.

1. Introduction

The research agenda of heterogeneous-agent models initiated by Huggett (1993) and Aiyagari (1994) has the advantage that it describes data and individual risks at the micro level, channeling incentives from the micro level to the macro level. In a general-equilibrium heterogeneous-agent model, the channel of analysis works also towards the opposite direction: from the macro level to the micro level, since aggregate resource constraints and prices affect individual budget constraints. In order to form their plans, agents in the model must predict future prices. A desirable property that can help in rationalizing choices made by agents is that agents are able to predict prices through observing and predicting only a limited set of macro aggregates, instead of having to address the dynamics of all moments of the income/wealth distribution.[1] The ability to sufficiently rely on aggregates as a tool for developing intuitive rules of thumb rests upon the presence of a representative consumer: a fictitious agent who is always endowed with the aggregate resources of a heterogeneous-agent economy and whose choices always coincide with economy-wide aggregated choices under any price regime. The use of particular utility functions such as constant-relative-risk-aversion (CRRA) utility is the key ingredient for achieving the existence of a representative consumer in a model.

While some studies provide sufficient conditions for the existence of a representative consumer, all assume that households have the same utility function.[2] It is not well understood whether the representative consumer can survive in a community where utility functions differ across households as well. This concern is important, as consumer decisions

---

[1] For example, see Krusell and Smith (1998), and Caselli and Ventura (2000).

[2] Examples of such studies are Chatterjee (1994), Atkeson and Ogaki (1996), Caselli and Ventura (2000), and Maliar and Maliar (2001, 2003). Krusell and Smith (1998) and Carroll (2000) examine cases of heterogeneity in rates of time preference, but they assume the same momentary-utility functions. Carroll (2000) is a study that investigates conditions under which approximate aggregation fails.

are made in the context of different household types. In particular, individuals living in multi-member households share goods within the household (housing, furniture, appliances, etc.) and achieve household-size economies. The potential benefits from household-size economies alter the objective functions of different household types, making the assumption that all households have the same utility function questionable.[3] In this paper we fully incorporate household-size heterogeneity in a macroeconomic analysis and examine, theoretically and empirically, whether the convenient strategy of using a representative consumer can be preserved or falsified.

Our theoretical contribution is that we allow for differences in the objective functions of households and we identify the comprehensive family of household objective functions that lead to the existence of a representative consumer. Once we identify the functional forms of household-type objective functions, we can distinguish the degree of parametric heterogeneity allowed. The theoretical answer we find is that household objective functions must be of the Stone-Geary form, and that the only parameters that can differ are household-type subsistence levels. In addition, the survival of the representative consumer relies upon a stringent regularity regarding household-size economies: once expenditures for subsistence needs are subtracted from disposable household income, household-size economies the remainder (discretionary) household incomes entail are the same across the rich and the poor. Empirically rejecting this stringent regularity falsifies the representative consumer construct as a whole.

We build the empirical test of the stringent regularity regarding household-size economies using micro data from the survey approach proposed by Koulovatianos, Schröder and Schmidt (2005, 2009). This is a survey of direct questions to respondents about equivalent incomes

---

[3] This concern may also be important for a growing literature relating family economics to macroeconomic activity through simulated models (see, for example, Aiyagari, Greenwood and Guner (2000), Greenwood and Seshadri (2002), and Greenwood et al. (2005)).

(EIs): household incomes that equate the level of material comfort of individuals living in households with different size (more or fewer members); if adding individuals to a household makes the within-household per-capita EI to drop, household-size economies have been achieved. So, since our survey method directly elicits EIs from respondents, it serves as a tool to directly measure household-size economies.

Our tests relying on representative survey data from Germany and several pilot surveys (conducted in countries as dissimilar as France, Cyprus, China, India, and Botswana, a total of 49 tests) do not reject the stringent requirement about the alignment of household-size economies across the rich and the poor.[4] Our German representative sample (2,024 respondents) also allows us to test the role of personal characteristics of survey respondents, which are not found to affect the effectiveness of our survey method. In addition, we have designed a follow-up survey questionnaire which poses the same assessment problem about EIs using different means of representation, in order to cross check whether respondents understand the survey's assessment problem, and we find affirmative evidence.

Our study does not prove the existence of a representative consumer. Yet, that our demanding test is unable to falsify the representative consumer on the grounds of household-type heterogeneity certainly lends support to using this convenient assumption in research. In addition, our analysis allows the quantitative construction of a precisely specified structural utility function of the representative consumer. For example, the output of our survey method enables one to use actual household-level micro consumer data in order to place individuals living in multi-member households in one-member household with incomes reflecting the same level of material comfort as they had before.[5] In an Aiyagari (1994) type of model

_____

[4] This alignment of household-size economies across the rich and the poor is empirically captured by an affine relationship among different levels of EIs across all household types. Since our survey method provides estimates of EIs, we are able to test this affine relationship through specification tests in regression analysis.

[5] See Additional Appendix D for details on the construction of such a distribution of incomes.

it is this new distribution of one-member-household equivalent incomes that is appropriate to be combined with the constructed representative-consumer utility function. In other words, the dimension of demographic heterogeneity can be reduced, and only income/asset heterogeneity can be retained, offering remarkable tractability.

Finally, as our estimates indicate the presence of nontrivial subsistence needs of consumption for all examined household types, future research may theoretically study the role of Stone-Geary preferences in macroeconomic applications. Moreover, empirical macroeconomists or demand-system microeconometric analysis may promote the existing literature of dealing with the estimation of household-type-specific subsistence needs in consumption.

2. Theoretical Results on Multidimensional Heterogeneity and the Existence of a Representative Consumer

In this section we fully characterize the class of utility functions of heterogeneous households that leads to the existence of a representative consumer: a fictitious consumer whose preferences represent an entire community-preference profile (the set of utility functions of all household types), and whose choices always coincide with actual aggregated choices under any price regime. Then, we show that the requirement that a representative consumer exists in the presence of household-size heterogeneity implies that equivalent incomes (EIs) are necessarily linked through a linear relationship. Our goal is to accommodate the additional dimension of household-size heterogeneity. So, the question we make is: how much heterogeneity in household objective functions can the representative consumer survive?

For a set of heterogeneous households that live for one period and decide once and for all about the consumption of different consumer goods, Gorman (1953) has shown that the indifference curves of a representative consumer are non-intersecting if, and only if, Engel curves for all traded commodities are always linear and parallel across all households for

any given price regime. In a later study Gorman (1961) has shown that, for Engel curves to be linear and parallel, utility functions must meet a particular functional property; this property has led Pollak (1971) to a complete characterization of the set of utility functions of households that allow the existence of a representative consumer, under the assumption that all utility functions are additively separable with respect to each different good. Concerning households that act for more than one period, in particular for households that are infinitely-lived dynasties, previous work has focused on households that consume a single composite consumer basket and accumulate financial wealth over time: Chatterjee (1994) and Caselli and Ventura (2000) have identified household utility functions that are sufficient for the existence of a representative consumer. Here we complete their work by showing the set of utility functions that is also *necessary* for the existence of a representative consumer (see Theorems 1 and 2 below). With these new comprehensive results, we can deduce that the existence of a representative consumer in the presence of household-size heterogeneity implies that different levels of EIs are necessarily linked through a linear relationship across different household types (see Proposition 1 below).

The core theoretical results on aggregation are split into two categories. The first category deals with dynasties where momentary utility functions are constant over time (Theorem 1). Theorem 1 results from weak conditions and it is directly related to our empirical tests, since in our survey we ask respondents to evaluate hypothetical households with exogenously fixed demographic composition. Since, however, dynasties may experience changing demographic composition, Theorem 2 extends the analysis to time-variant momentary utility functions. Theorem 2 identifies which parameters of the resulting Stone-Geary preferences are allowed to vary over time and which are not, which is a novel result of this paper. Yet, assumptions behind Theorem 2 are tighter compared to these of Theorem 1, and a part of the proof of

Theorem 2 relies upon the proof approach of Theorem 1. For this reason, instead of moving to the statement and proof of Theorem 2 directly, we present the two results in two sections below. We are not aware of studies examining the necessary and sufficient conditions for linear aggregation in a setting where consumers are forward-looking.

2.1 Common Choice-Independent Rates of Time Preference and Time-Invariant Momentary Utility Functions

Time is continuous and the time horizon is infinite, $t \in [0, \infty)$. Households are all infinitely-lived and comprise a constant set $\mathcal{I}$ of different types, with generic element i. The set of household types can be countable, finite, or a continuum. It can also be that all households are of the same type, and in any case there is a "large" number of households, making each of them having negligible impact on the aggregate economy, i.e., all households are price-takers. Assume a measure $\mu : \mathcal{I} \to [0, 1]$, which has a density, $d\mu$, with,

$$\inf \{ d\mu(i) \mid i \in \mathcal{I} \} > 0 . \tag{1}$$

So, if $\mathcal{I}$ is finite, $d\mu(i) > 0$ for all $i \in \mathcal{I}$, whereas if $\mathcal{I}$ is a compact interval, $d\mu(i)$ is continuous on $\mathcal{I}$ and bounded away from 0. Households of different types can differ with respect to their initial endowment of capital claims (assets) and also with respect to their labor productivity which is given by the exogenous function of time, $\theta^i : \mathbb{R}_+ \to \mathbb{R}_+$. Asset holdings for household $i \in \mathcal{I}$ at time 0 are denoted as a_0^i.[6]

There is a single private consumable good. Household preferences of each $i \in \mathcal{I}$, are given by the general additively-separable utility function with a common across households

---

[6] With slight abuse of notation, we assume that a community preference profile given by a set of utility functions $\left(U^i \right)_{i \in \mathcal{I}}$, is fixed, while within a preference group $i \in \mathcal{I}$, there can be many individuals with heterogeneous initial endowments a_0^j, and labor-productivity functions, θ^j. Instead of distinguishing individuals across groups through a multi-dimensional measure (e.g. $\tilde{\mu}(i, j)$, where i denotes the utility group and j denotes a single household unit with $\left(a_0^j, \theta^j \right)$), we resort to the reduced notation recommended above.

rate of time preference captured by the positively-valued function $\rho : \mathbb{R}_+ \rightarrow \mathbb{R}_{++}$, where

$$U^i \left(\left(c^i \left(t \right) \right)_{t \geq 0} \right) = \int_0^\infty e^{- \int_0^t \rho(\tau) d\tau} u^i \left(c^i \left(t \right) \right) dt \; . \tag{2}$$

Assumption 1 *For all $i \in \mathcal{I}$, $u^i : \mathbb{R}_+ \rightarrow \mathbb{R}$, is twice-continuously differentiable and such that $u_1^i \left(c \right) > 0$ and $u_{11}^i \left(c \right) < 0$ on some interval, $\mathbb{C}^i \subseteq \mathbb{R}_+$, with both $u_1^i \left(c \right) < \infty$ and $-\infty < u_{11}^i \left(c \right)$ for all $c \in \mathbb{C}^i \subseteq \mathbb{R}_+$, with $\underline{c}^i \equiv \inf \left(\mathbb{C}^i \right) < \sup \left(\mathbb{C}^i \right) \equiv \bar{c}^i$.*

Assumption 1 secures that, for all $i \in \mathcal{I}$, there is a choice domain, $\mathbb{C}^i \subseteq \mathbb{R}_+$, which is an interval, and where standard desirable properties of momentary utility functions are present. Assumption 2 allows households to choose consumption paths such that, asymptotically, the consumption level is non-decreasing.

Assumption 2 $\int_0^\infty e^{- \int_0^t \rho(\tau) d\tau} dt < \infty$.

All households are endowed with the same amount of time at each instant, supplied for labor inelastically. The momentary time endowment is normalized to one, without leading to loss of generality: if a household is larger and more than one members work, given that labor supply is inelastic, personal labor incomes within the household can be summed up and the household's total labor income can be used instead.

For any given price vector $\left(r \left(t \right), w \left(t \right) \right)_{t \geq 0} >> 0$, with $r \left(t \right)$ being the interest rate and $w \left(t \right)$ the labor wage per unit of time at each instant, the budget constraint faced by household $i \in \mathcal{I}$ is,

$$\dot{a}^i \left(t \right) = r \left(t \right) a^i \left(t \right) + \theta^i \left(t \right) w \left(t \right) - c^i \left(t \right) \; , \tag{3}$$

for all $t \geq 0$, ($\dot{x} \left(t \right) \equiv dx \left(t \right) / dt$ for any variable x) and the transversality condition is,

$$\lim_{t \rightarrow \infty} e^{- \int_0^t r(\tau) d\tau} a^i \left(t \right) = 0 \; . \tag{4}$$

We define the domains of wealth- and productivity heterogeneity at any given price vector, for which the existence of a representative consumer is conceptually relevant. That is the domain that guarantees interiority of solutions to each individual optimization problem. The following assumption states this formally.

Assumption 3 *Given a community preference profile captured by the collection of functions $(u^i)_{i \in \mathcal{I}}$ and ρ, the domain of, (i) initial distribution of assets $(a_0^i)_{i \in \mathcal{I}}$, (ii) the collection of labor-productivity functions $(\theta^i)_{i \in \mathcal{I}}$, and (iii) prices $(r(t), w(t))_{t \geq 0}$, is restricted so that the optimization problems of all households $i \in \mathcal{I}$ are well-defined, and the solution to each individual problem is interior for all $t \geq 0$.*

Given Assumption 3, maximizing (2) subject to constraints (3) and (4) for any given a_0^i is an optimal-control problem with necessary optimality conditions given by,

$$\dot{c}^i(t) = -\frac{u_1^i(c^i(t))}{u_{11}^i(c^i(t))}[r(t) - \rho(t)] \ , \tag{5}$$

together with (3) and (4), that lead to decision rules of the form,

$$c^i(t) = C^i\left(a^i(t), t \,\Big|\, (r(\tau), w(\tau), \theta^i(\tau))_{\tau \geq t}\right) \ , \tag{6}$$

i.e., consumption rules at each moment are memoryless, depending only on current personal assets and current and future prices. Assumptions 1 and 3 have a particular connection, that is revealed from equation (5). The term $-\frac{u_1^i(c^i(t))}{u_{11}^i(c^i(t))}$ must always be well-defined in order to have interiority. Thus, to meet Assumption 3 (interior solutions), it is necessary that $c^i(t) \in \mathbb{C}^i$, for all $t \geq 0$, and all $i \in \mathcal{I}$.

Definition 1 *Given a community preference profile captured by the collection of functions $(u^i)_{i \in \mathcal{I}}$, and ρ, complying with Assumptions 1 and 2, a representative consumer (denoted by "RC") is a (fictitious) consumer who has time-separable preferences, $\int_0^\infty v^{RC}(c(t),t)\,dt$, with $v_1^{RC}(c,t)$, $v_{11}^{RC}(c,t)$ and $v_{12}^{RC}(c,t)$ existing, and with $0 < v_1^{RC}(c,t) < \infty$ and $-\infty < v_{11}^{RC}(c,t), v_{12}^{RC}(c,t)$ well-defined for all consumption levels, $c \in \mathbb{C}^{RC} \equiv \left\{ c \in \mathbb{R}_+ \,\middle|\, c = \int_{\mathcal{I}} c^i d\mu(i) \;,\; c^i \in \mathbb{C}^i,\, i \in \mathcal{I} \right\}$, for all $t \geq 0$, and who possesses the economy-wide aggregate wealth and productivity at all times, and whose demand functions coincide with the aggregate demand functions of the economy at all times, namely,*

$$c^{RC}(t) = C^{RC}\left(\int_{\mathcal{I}} a^i(t)\,d\mu(i)\,,\,t\,\middle|\, \left(r(\tau), w(\tau), \int_{\mathcal{I}} \theta^i(\tau)\,d\mu(i) \right)_{\tau \geq t} \right) =$$

$$= \int_{\mathcal{I}} C^i\left(a^i(t)\,,\,t\,\middle|\, \left(r(\tau), w(\tau), \theta^i(\tau) \right)_{\tau \geq t} \right) d\mu(i)\,, \qquad (7)$$

for all $t \geq 0$, for the complete domain of prices $(r(t), w(t))_{t \geq 0}$, initial distributions of assets, $(a_0^i)_{i \in \mathcal{I}}$, and functions $(\theta^i : \mathbb{R}_+ \to \mathbb{R})_{i \in \mathcal{I}}$ that comply with Assumption 3.

This is a rather strong representative-consumer concept: it focuses on solving only one household's problem using standard optimal-control techniques, in order to derive aggregate demands at all times.[7] Our goal is to examine conditions on the community preference profile that are necessary and sufficient for the existence of social preferences (representative-consumer preferences) consistent with the independence axiom of Koopmans (1960): if two different intertemporal paths have a common outcome at a certain point in time, preferences

---

[7] Our aggregation concept differs from the aggregation concept used by Gollier and Zeckhauser (2005) who use Pareto weights to construct the objective of a "representative agent".

over these two paths should always, and solely, be determined by comparing them with remaining outcomes at that particular date that differ. In other words, the focus of our analysis is to characterize community preference profiles where social preferences are time-separable and, at each separate point in time, non-intersecting social indifference curves exist.

Assumption 4 $\underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i$ *is non-empty and not a singleton.*

Assumption 4 places a weak constraint on the scope of preference heterogeneity. It says that nobody's bliss point (if any), should be lower than or equal to anyone else's subsistence level of consumption (if any), hence $\underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i$ is an interval. Since the consumable good is considered to be a composite good (a consumer basket), Assumption 4 is not unreasonably restrictive.

Theorem 1 *Under Assumptions 1 through 4, a representative consumer exists if and only if*

$$
u^i(c) =
\begin{cases}
\frac{(\alpha c + \beta_i)^{1 - \frac{1}{\alpha}} - 1}{\alpha \left(1 - \frac{1}{\alpha}\right)} & \text{with } \alpha > 0 \text{ and } \beta_i \in \mathbb{R} \text{ or } \alpha < 0 \text{ and } \beta_i > 0 \\
\text{or} & \\
-e^{-\frac{1}{\beta_i} c} & \text{with } \beta_i > 0
\end{cases}
,
$$

(8)

for all $i \in \mathcal{I}$. The representative consumer has the common, across households,

rate of time preference, $\rho(t)$, at all times, and momentary utility function given

by,

$$u^{RC}(c) = \begin{cases} \frac{(\alpha c + \beta_{RC})^{1-\frac{1}{\alpha}} - 1}{\alpha\left(1-\frac{1}{\alpha}\right)} & \text{for } \alpha \neq 0 \\ -e^{-\frac{1}{\beta_{RC}}c} & \text{else} \end{cases}, \qquad (9)$$

with

$$\beta_{RC} = \int_{\mathcal{I}} \beta_i d\mu(i) .$$

Proof Theorem 1 See the Appendix.□

Theorem 1 states comprehensively that the existence of a representative consumer rests upon particular functional forms and common parameter values: the quasi elasticity of intertemporal substitution, α, should be the same across all households;[8] households can differ only with respect to their subsistence consumption or bliss point of consumption; yet, it is either that all households have some subsistence consumption, or that all households have some bliss point, but bliss points and consumption subsistence levels cannot coexist in the same community preference profile.

These restrictions on the community preference profile, $(u^i)_{i \in \mathcal{I}}$, lead to *common orientation of incentives and actions of rich and poor, or large versus small, households.* In particular, the *consumption decision rules* of all household types, $i \in \mathcal{I}$, are of the form,

$$c^i(t) = b(t) a^i(t) + \zeta^i(t) ,$$

---

[8] Notice that the elasticity of substitution is equal to $\alpha \cdot (1 - \beta_i/c)$.

i.e., they *are always linear in financial wealth, $a^i(t)$, and parallel across all households* (see the sufficiency part in the proof of Theorem 1 in the Appendix).[9] Yet, in order to accommodate the idea that households may switch type over time, in the next section we explore the case where momentary utility is time-variant.

2.2 Time-Variant Momentary Utility Functions

We examine the case where individual rates of time preference have a consumption-choice-independent part which is common-across agents, and a consumption-choice-dependent part implied by their momentary utility function.[10] In particular, consumer preferences of each $i \in \mathcal{I}$, are given by the general additively-separable utility function,

$$U^i\left(\left(c^i(t)\right)_{t\geq 0}\right) = \int_0^\infty e^{-\int_0^t \rho(\tau)d\tau} u^i\left(c^i(t),t\right) dt \ . \tag{10}$$

with $\rho : \mathbb{R}_+ \to \mathbb{R}_{++}$. A sequence of assumptions are important for the analysis that follows.

Assumption 5 *For all $i \in \mathcal{I}$, and all $t \geq 0$, $u^i : \mathbb{R}_+^2 \to \mathbb{R}$, is twice-continuously differentiable with respect to c, once continuously differentiable with respect to t, and such that $u_1^i(c,t) > 0$ and $u_{11}^i(c) < 0$ on some interval, $\mathbb{C}^i(t) \subseteq \mathbb{R}_+$, with $u_1^i(c) < \infty$, $-\infty < u_{11}^i(c)$, $-\infty < u_{12}^i(c) < \infty$ for all $c \in \mathbb{C}^i(t) \subseteq \mathbb{R}_+$, with $\underline{c}^i(t) \equiv \inf(\mathbb{C}^i(t)) < \sup(\mathbb{C}^i(t)) \equiv \bar{c}^i(t)$.*

Assumption 6 *For all $i \in \mathcal{I}$, $\underset{t \geq 0}{\cap} u_1^i(\mathbb{C}^i(t),t)$ is non-empty and not a singleton.*

Assumption 7 *For any $i \in \mathcal{I}$, let,*

$$\mathfrak{C}^i \equiv \left\{ c \in \underset{t\geq 0}{\cap}\mathbb{C}^i(t) \ \middle| \ \underset{t\geq 0}{\cap} u_1^i\left(\mathbb{C}^i(t),t\right) \text{ is non-empty and not a singleton} \right\} \ .$$

---

[9] Carroll and Kimball (1996) show that if labor income uncertainty is introduced, the consumption function becomes convave. Nevertheless, the class of preferences we have identified promotes a linear shape for the consumption function, at least when wealth is sufficiently far from borrowing constraints.

[10] Koulovatianos (2005, Theorem 2) provides an analysis for a class of utility functions that allows for heterogeneous choice-independent rates of time preference. The necessary class of utility functions allowing for linear aggregation is very restricted: it is utility functions with constant absolute risk aversion.

Then, $\bigcap\limits_{i \in \mathcal{I}} \mathfrak{C}^i$ is non-empty and not a singleton.

Based on these assumptions, Theorem 2 states an aggregation result that pertains to this setting.

Theorem 2 *Under Assumptions 2, 3, and 5 through 7, a representative consumer exists if and only if*

$$
u^i(c,t) = \begin{cases} \dfrac{\left(\alpha c + \beta^i(t)\right)^{1-\frac{1}{\alpha}}-1}{\alpha\left(1-\frac{1}{\alpha}\right)} & \text{with } \alpha > 0 \text{ and } \beta^i(t) \in \mathbb{R} \text{ or } \alpha < 0 \text{ and } \beta^i(t) > 0 \\[4mm] \text{or} & \\[2mm] -e^{-\frac{1}{\beta_i G(t)}c} & \text{with } \beta_i > 0 \end{cases} ,
$$

(11)

for all $i \in \mathcal{I}$, with functions $\beta^i(t)$ such that Assumptions 6 and 7 are met.

The representative consumer has

$$
U^{RC}\left((c(t))_{t \geq 0}\right) = \int_0^{\infty} e^{-\int_0^t \rho(\tau)d\tau} u^{RC}\left(c(t),t\right) dt ,
$$

(12)

with,

$$
u^{RC}(c,t) = \begin{cases} \dfrac{\left(\alpha c + \beta^{RC}(t)\right)^{1-\frac{1}{\alpha}}-1}{\alpha\left(1-\frac{1}{\alpha}\right)} & \text{for } \alpha \neq 0 , \quad \beta^{RC}(t) = \int_{\mathcal{I}} \beta^i(t) d\mu(i) \\[2mm] -e^{-\frac{1}{\beta_{RC}G(t)}c} & \text{else, } \quad \beta_{RC} = \int_{\mathcal{I}} \beta_i d\mu(i) \end{cases} .
$$

(13)

Proof Theorem 2 See the Appendix.□

The message conveyed by Theorem 2 and the additional insight to Theorem 1 is that *parameter α is not only common across all household types, but also α cannot vary over*

time. The only utility parameters that can vary over time are subsistence levels (or bliss points) $\beta^i(t)$.

2.3 Application to Household-Size Heterogeneity and the Necessity of the Linear Relationship Across EIs

Consider the unitary-model for households (see, for example, Vermeulen, 2002), that individuals in multi-member households maximize a common objective function, a standard assumption in macroeconomics literature. Moreover, for simplicity, assume that $\rho(t) = \rho$ for all t, another standard assumption in the literature, and also that households of the same size all have the same utility function. If a representative consumer exists, then utility functions should fall in the class given by Theorem 1. Focusing on the case where $r(t) = \bar{r} = \rho$ for all t, and with $w(t) = \bar{w}$, and $\theta^i(t) = \bar{\theta}^i$ for all t, a steady-state condition for all households, (5) and (3) imply that

$$\bar{c}^i = \bar{r}a^i + \bar{w}\bar{\theta}^i = \bar{y}^i \ , \tag{14}$$

where $\bar{y}^i$ is the permanent income of household i in the steady state.[11] Moreover, we assume that each household type stays the same forever, with $\beta^i(t) = \beta_i$, for all $t \geq 0$, when preferences of Theorem 2 apply. So, the model referring to Theorem 2 above collapses to the model of Theorem 1.[12] On such a permanent income trajectory, the lifetime utility of a household is $\int_0^\infty e^{-\rho t} u^i(\bar{y}^i)\,dt = u^i(\bar{y}^i)/\rho$. We define a set of *permanent equivalent incomes*, denoted by $\bar{y}_E$, of households belonging to any two different family types $i, j \in \mathcal{I}$, as incomes that equate lifetime utilities, $u^i(\bar{y}^i)/\rho = u^j(\bar{y}^j)/\rho$, i.e. any pair $(\bar{y}^i_E, \bar{y}^j_E)$, $i, j \in \mathcal{I}$, that solves

$$u^i(\bar{y}^i_E) = u^j(\bar{y}^j_E) \ . \tag{15}$$

---

[11]In the empirical analysis below it can be seen that the way we have designed our survey questionnaire, asking respondents about monthly incomes, approximates the above steady state conditions where households consume their incomes.

[12]The interpretation of the model of Theorem 2 is the case where a dynasty is shifting from one household type to another over time, keeping smoothness of such transitions so as to comply with Assumption 5.

In Proposition 1 which appears below we present a result that holds under the above steady-state conditions. In Section 3 we empirically implement a survey instrument that mimics such a stringently controlled environment. In particular, we ask our respondents questions about evaluating the material comfort of individuals living under hypothetical exogenously fixed conditions: individuals who live in households with particular demographic composition and who receive particular levels of monthly household income streams. So, the empirical relevance of the restrictive assumptions made in Proposition 1 is that our survey instrument is capable of controlling hypothetical situations of households, mimicking and approximating steady state conditions where households consume their incomes.

Proposition 1 *Let the unitary household model hold, and let all households of the same size have the same utility function. If $r(t) = \bar{r} = \rho$ for all $t \geq 0$, and all household types receive their permanent incomes $\bar{y}^i$ for all $i \in \mathcal{I}$. Then if each household type stays the same forever, with $\beta^i(t) = \beta_i$, for all $t \geq 0$, the existence of a representative consumer implies that for all $i, j \in \mathcal{I}$,*

$$\bar{y}_E^j = \chi_{i,j} + \psi_{i,j} \bar{y}_E^i \, , \tag{16}$$

for some $\chi_{i,j} \in \mathbb{R}$, and $\psi_{i,j} > 0$.

Proof See the Appendix.□

In words, equation (16) means that if all household types are in a zero-growth steady state where they receive their permanent income, then *household size-economies entailed in discretionary incomes (income minus subsistence needs) are the same across the rich and the poor.*[13] Corollary 1 is an immediate consequence of Proposition 1, that we state without proof.

---

[13]We remind that in this case where households are in a zero-growth steady state ($r(t) = \bar{r} = \rho$), and receiving their permanent income, households optimally choose to spend their discretionary income at every

Corollary 1 *Empirically falsifying equation (16), falsifies the existence of a representative consumer.*

Corollary 1 shows that testing the existence of the whole representative-consumer construct in the strict linear-aggregation sense invented by Gorman (1953), can collapse through the testing of a single equation, equation (16). Throughout the rest of this paper we claim that equation (16) is testable, we demonstrate how it can be tested, and we put it under scrutiny.

3. Empirical Analysis

Identifying household incomes that equalize material comfort across household types is a challenging task. This task has occupied researchers working on inequality measurement since long ago.[14] Most past work uses demand systems in order to impose a theoretical framework that identifies which household incomes make the material comfort of household members equal. In Buhmann et al. (1988) it is documented that estimates are highly sensitive to both working assumptions underlying demand systems and to definitions of consumption categories.[15] Other approaches outlined in Buhmann et al. (1988) reconfirm the

---

instant of time. For some ξ, equation (16) can be re-written as

$$y^j - \xi \cdot \chi_{i,j} = \psi_{i,j} \left(y^i - \frac{\xi - 1}{\psi_{i,j}} \chi_{i,j} \right) \ ,$$

where ξ is to be identified empirically, and it will specify subsistence needs for the two types. In our empirical analysis in the next section we find that, if i in the equation right above is a one-member household, then $\chi_{i,j} > 0$ in all cases. That $\chi_{i,j} > 0$ in all cases where j is a multi-member household implies that there are subsistence needs which increase as household members are added in the household, and it motivates that $\xi > 1$ (each household has non-trivial subsistence needs). In the above equation $\psi_{i,j}$ measures the economies of household size achieved by discretionary incomes across household types i and j, and the equation implies that these are the same for the rich and the poor.

[14]A key objective in inequality measurement is to utilize available income data at the household level in order to construct measures of incomes that are one-member-household equivalent. In this way the distribution of living standards across *individuals* can be measured from an observed distribution of household incomes.

[15]In demand system analysis, one issue is underidentification, which researchers overcome throuh making specific assumptions about functional relationships linking EIs. For example, Lewbel (1989) and Blackorby

lack of robustness of EI estimates and the lack of consensus among specialists on a method to estimate EIs. So, for example, the OECD and the U.S. Bureau of Labor Statistics (BLS) use an expert who assigns EIs to different household types relying on her/his intuition, insights, and familiarity with descriptive statistics from household data. Still, experts disagree.[16] For these reasons we have designed a survey method where we ask respondents to provide their own assessments of EIs for a set of household types. Specifically, we ask respondents: "What is the net monthly household income that can make a household with two adults and a child attain the same level of material comfort as that of a one-member household with a net monthly income of $2,000?".[17]

The motivation of our survey relies on the idea that respondents are experienced at recognizing the connection between a household's demographic composition and the level of material comfort that income can buy for its members. In this sense, respondents are 'real-life experts' in assessing EIs. Pooling diverse insights of a large number of respondents may correct potential biases of a single expert. Yet, respondents must have sufficient information to assess EIs for households with a demographic composition and a level of material comfort that differ from their own actual experiences. Otherwise, estimates of EI may suffer from limited information bias (LIB). In order to test for LIB we use a large sample that is representative with respect to the income dimension and oversamples household types that are scarce in the overall population (for example, single parents with two or more children).

and Donaldson (1993) assume a special case of (16) where $\chi_{i,j} = 0$, in order to identify EIs, while Donaldson and Pendakur (2006) impose (16) in their estimation. Yet, these assumptions are a-priori untestable.
[16]See the relevant OECD website (also appearing in references) at:
    http://www.oecd.org/LongAbstract/0,2546,en_2825_497118_35411112_1_1_1_1,00.html.
[17]Another important aspect of approaching this demanding estimation task is that the validity of equation (16) requires to distinguish experiences where a household receives its permanent income every period. Identifying such a special intertemporal income profile with constant income receipts in actual data is difficult and it restricts possibilities of performing this test. Our survey instrument serves as a control device where respondents are asked to perform a particular thought experiment that replicates the income profile behind equation (16).

Moreover, respondents should demonstrate sufficient understanding in answering the question about assessing EIs. To test for this crucial aspect of survey effectiveness, we also pose an equivalent assessment problem using different means of representation, and then cross-check for consistency. So, our survey instrument is equipped with a tool that tests whether people 'mean what they say'.[18]

3.1 Overview of Survey Design

Our questionnaire consists of two main parts.[19]   In Part A, we pre-assign a net monthly income for a one-member household, a reference income (RI), and ask respondents to state EIs for seven other household types. Each respondent is randomly assigned one of five different RIs. The question asked is of the following type: "What is the net monthly household income that can make a household with two adults and a child attain the same level of material comfort as that of a one-member household with a net monthly income of $2,000? What income would one need if, instead, there were two children in the household?"[20] We emphasize that we use *material comfort* or living standard, as measured by the goods, services, and luxuries available to an individual or group, which should be distinguished from the concept of overall life satisfaction used in Kahneman and Krueger (2006) and Kahneman et al. (2006).

In Part B we pose an equivalent assessment problem to this of Part A, using different means of representation to cross-check for consistency: Likert-scale evaluations of material

---

[18]See, for example, Bertrand and Mullainathan (2001) for a discussion of the validity of respondent data in surveys.

[19]Our questionnaire appears in Appendix E.

[20]A crucial aspect in the design of Part A is which RIs to choose. In Appendix A we explain in detail how we have calibrated the five different levels of RI combining information from the actual German income distribution of one-member households and information about social benefits for the poorest households in Germany. In our surveys we have calibrated RIs by picking five incomes that span the range from the 5th up to the 95th percentile of the one-member-household distribution of disposable income and split it in four equi-spaced segments.

comfort.[21] The question we ask is: "Consider that the net monthly household income of a household with two adults and one child is \$5,500. State a number from 1 to 100 that best characterizes the level of material comfort of this household, given that '10' is 'very bad,' '50' is 'sufficient,' and '90' is 'very good."' Respondents receive such a question for the one-member household and the seven household types of Part A. Household incomes evaluated in Part B were obtained through a previous pilot study in Germany using the same RIs as in Part A.[22] If a respondent states a Likert-scale value for a household type with pre-assigned income Y that is higher than what she/he stated for the one-member household with the RI in Part B, then, in Part A, this respondent should have stated an EI for that household type that is lower than Y.

3.2   Survey Samples

In our empirical analysis we use a large sample of 2,042 respondents from Germany collected in year 2006. Details about data collection and personal characteristics of respondents appear in Appendix A. This large sample is from all regions of Germany and it is representatively sampled along the dimension of household incomes. Yet, in order to secure sufficient power of LIB tests, we have over-sampled single parents with two or more children, and all relevant details also appear in Appendix A. The intended over-representation of respondents having children has contributed considerably to the high percentage of female respondents.

Previously to conducting this large German survey we have run six pilot studies in countries as different as Botswana, China, Cyprus, France, Germany, and India. There is a key difference in survey design between the large German survey and the six pilot surveys. In the large German survey, in Part A, each respondent was asked to provide EIs for seven

---

[21]For an example of Likert-scale evaluations see Kahneman et al. (2004).
[22]The previous pilot study is the German data appearing in Koulovatianos et al. (2005).

household types, all referring to the a single randomly selected RI (out of five available RIs). In the six pilot studies, each respondent has been asked to do the same, but for all five RIs, i.e., each respondent has provided 35 EI assessments in total.[23] This is a reason why our small pilot samples (ranging from 130 to 223 respondents) are sufficient. In addition, the pilot surveys do not include part B of the questionnaire.

3.3 What the Raw Data Say

The scatter plots of uncontrolled (raw) responses in Part A of the survey appear in Figure 1. Each panel refers to a household type distinguished by demographic composition. On the horizontal axis of each panel is the one-member household income (RI), five fixed levels that are exogenously determined in the questionnaire (amounts are in 2006 Euros). Against these fixed RIs we plot the survey responses about EIs. In each panel there are 2,042 scatter points, each corresponding to a response by each of our 2,042 respondents. So, in each panel there is one EI assessment by each respondent. Crucial for the test of the affine relationship given by (16) is that *in each panel of Figure 1, the group of respondents corresponding to each RI (each vertical scatter) is independent (disjoint) from all other respondent groups that stated EI assessments for different RIs (about 400 respondents for each RI).*

Each panel of Figure 1 suggests that the relationship between EI and RI is affine: for all seven household types, a sixth-degree polynomial least-squares curve (solid line) is hardly distinguishable from a linear fit (dashed line). Only for the fourth RI (EUR 2,750), the polynomial fit indicates a slight deviation downwards. In brief, *Figure 1 suggests that five independent groups of respondents seem to place their assessments of EIs on a straight line for seven different household types, on average.*

---

[23]The only exception is Botswana, where three instead of five RIs have been provided (see Appendix B for details).

The affine relationship among EIs is also present in all pilot studies appearing in Figures 2 and 3 (raw responses again). The structure of Figures 2 and 3 is the same as this in Figure 1, with the sole difference that we have merged scatter plots from three countries in each figure and that we present only sixth-degree polynomial fits (and not linear fits as it is the case with the dashed lines appearing in Figure 1). For inter-country comparisons all amounts appearing in Figures 2 and 3 are in purchasing-power-parity (PPP) adjusted Euros for Germany in year 2006. In all panels of Figures 2 and 3 the sixth-degree polynomial fit is visually close to a line. Nevertheless, we remind that in our pilot studies, each respondent provided assessments for all five RIs for each household type. So, in each panel of Figures 2 and 3 one respondent (per country) has provided five scatter points (EI assessments), one for each RI.

Regarding our pilot surveys, an objection can arise concerning the validity of our tests about affine relationship (16). If each respondent follows an affine rule of thumb to provide EI assessments, the average picture in each country could have been a result of framing: respondents may be lazy to think and perhaps follow an affine rule of thumb that dominates the total picture. For such reasons we have designed the large German survey in order to test whether respondents think and mean what they say, and with independent groups of respondents assessing EIs for each RI. We devote the remainder of this section to providing formal tests of (16), and for the effectiveness of our survey method.

3.4   Regression Analysis

3.4.1   Overview of Goals

Our empirical analysis has four goals. First, we perform a specification test for the affine relationship given by (16). We assume (16) as candidate specification in household-type specific regression models where stated EIs are the endogenous variable and RIs are the

exogenous variable. We also assign additional dummy variables for RIs, so as to test if there is any variation left unexplained by the affine relationship given by (16).

Our second goal is to test whether respondents "mean what they say", i.e. if they understand the context of the questions correctly. As we have explained above, in Parts A and B of the questionnaire we have provided the same assessment problem using different means of representation. So, we construct a variable capable of cross-checking for consistency between responses of the same respondent in Parts A and B.

Our third goal is to test whether the rich sufficiently understand the needs of the poor and whether the poor understand the wants of the rich, i.e., whether respondents understand the determinants of material comfort of individuals living in family types different from the respondent's family type. If this understanding is limited, then responses may suffer from LIB. To test for LIB, answers from respondents who state an EI for the household type and/or living standard that is the same as their own, are distinguished from answers where this is not the case. The presence of LIB is tested in regression analysis through a test of exclusion of dummy variables that identify this relationship between respondents' personal characteristics and the features of households that respondents evaluate.

Our fourth goal is to test whether personal characteristics of respondents affect their assessments. So, in regression analysis we use a large set of personal characteristics of the respondents as conditioning variables and test for their potential impact. Since sampling is representative in the large sample for Germany, these tests should have sufficient statistical power.

3.4.2 Regression Model and Results

Our regression model for the large survey from Germany is,

$$ES_i^h = f^h\left(RI_i\right) + b_0^h RI\_Dummies_i + b_1^h NLSE_i^h + b_2^h LIB_{h,i} + b_3^h LIB_{mc,i}$$

$$+ b_4^h\left(LIB_{h,i} \cdot LIB_{mc,i}\right) + b_5^h Personal\_Characteristics_i + \varepsilon_i^h \ , \tag{17}$$

where

$$f^h\left(RI\right) = a^h + \frac{b^h}{RI} \ . \tag{18}$$

The dependent variable is defined as,

$$ES_i^h = \frac{EI_i^h}{RI_i}$$

where EI_i^h is the EI stated by respondent i about household type h, given that respondent i was asked to state EIs using a one-member household with RI equal to RI_i as a benchmark. Because an EI divided by RI is an Equivalence Scale (ES), ES_i^h is i's assessment of the ES concerning household type h, given the RI level that was assigned to i in Part A of the questionnaire.

The function $f^h\left(RI_i\right)$ given by (18) in equation (17) is a proposed candidate for offering an accurate explanation of the relationship between RIs and ESs and complies with (16). The term ε_i^h is the error term. Definitions and roles of all conditioning variables in equation (17) appear below.

Variable $RI\_Dummies_i$: testing the affine relationship (16). This is a set that can include up to three dummy variables related to RI_i, the RI assigned to respondent i in Part A.[24] If, for example, the RI equal to EUR 2,000 is included in this set, then the *RI_Dummy(=EUR 2,000)* takes the value of 1 for all respondents who where assigned RI

---

[24]The set $RI\_Dummies_i$ can contain up to three RI dummy variables, since four RI dummy variables together with a constant (a^h) are perfectly correlated with the monotonic function b^h/RI.

equal to 2,000 EUR, and 0 otherwise. The conditioning set $RI\_Dummies_i$ is the instrument for conducting the specification test for any candidate function $f^h(RI)$: if there is any variation left unexplained by the affine relationship (16) that is now transformed into (18) in regression (17), then it should be captured by $RI\_Dummies_i$; so a test of exclusion of $RI\_Dummies_i$ reveals whether $f^h(RI)$ satisfactorily captures the dependence of ESs on RI. In Table 1 most of these RI dummy variables are insignificant. Only the RI dummy variable at RI = EUR 2,750 is significant (based on t-tests), but it suggests only a small deviation from the affine relationship (16). The exclusion tests concerning all three RI dummy variables have moderately low F-test statistics. *None of these tests rejects exclusion with a confidence level of 99% or more.* In sum, given how tough this test of exclusion is, equation (18) gives a reasonable specification for $f^h(RI)$, which has meaningful intuition. Coefficient b^h in (18) can be interpreted as fixed costs in consumption, *in addition* to the fixed costs of the one-member household. The constant a^h in equation (18) is a measure of household-size economies after controlling for the presence of household-type specific fixed costs in consumption. As household income increases, fixed costs become a smaller share of a household's budget. In other words, ES is a *decreasing* function of RI.

Variable $NLSE_i^h$: testing whether respondents "mean what they say". The acronym NLSE stands for "Normalized Likert Scale Evaluation", and the NLSE value of respondent i for a household type h is given by,

$$NLSE_i^h = \ln\left(\frac{L_i^h}{L_i^*}\right)$$

where L_i^h denotes respondent i's stated Likert-scale value for household type h, and L_i^* denotes the Likert-scale value *given by the same respondent, i,* for the one-member household in Part B of the questionnaire. Each respondent was provided with only one RI to evaluate in

Part B, again randomly assigned.[25] The NLSE uses the stated Likert-scale value concerning the one-member household as a benchmark, and measures the deviation of each other Likert-scale value stated by the same respondent from this benchmark. In Appendix D we provide evidence that the NLSE is effective in suppressing noise from *Heterogeneity in Respondent Perceptions of Verbal Characterizations*.[26] If the sign of b_1^h in regression (17) is negative, then a necessary condition behind the hypothesis that respondents understand the main evaluation task in Part A finds affirming evidence. Moreover, the estimator of b_1^h may control for some respondents' deviant opinions about, e.g., the cost of partners or children, so a test of exclusion of the NLSE in the regression provides information about the possible presence of such deviant evaluations.[27] In Table 1 we can see that all NLSE coefficients have a negative sign and all tests of exclusion are rejected (P<0.001). These findings support the effectiveness of the survey method. Moreover, the size of all NLSE coefficients is small, indicating that respondents' deviant opinions about household-size economies do not affect the estimators of coefficients of equation (18) to a large extent.

$LIB_{h,i}$, $LIB_{mc,i}$, $(LIB_{h,i} \cdot LIB_{mc,i})$: *testing whether respondents understand the living*

---

[25]The RIs in Part A are assigned independently from those assigned in Part B. This feature of the survey design helps to avoid the possibility that the NLSE is spuriously correlated with the dependent variable in the regression analysis appearing in Table 1 in the text. Spurious correlation may result from having the same respondent focusing on the same level of material comfort in the evaluations of Parts A and B: some respondents may consciously attempt to provide consistent responses between Parts A and B, instead of focusing on the evaluation question in each Part.

[26]Heterogeneity in the way respondents perceive words is discussed in Appendix C. Kahneman and Krueger (2006, pp. 19-21) discuss this issue and propose a technique for coping with this problem in their analysis that uses Likert scales on verbal descriptions of well-being (although, as we have explained above, the concept of well being we use in our survey is material comfort instead of "happiness"). Similar concerns are also discussed in Bertrand and Mullainathan (2001). In Appendix C we present evidence on how our NLSE varible deals with this problem of stated Likert scale evaluations by repondents.

[27]See Pollak and Wales (1979) for concerns about consumer choices and fertility preferences. For example, biases stemming from any possible, say, dislike about children by respondents may be corrected by the inclusion of NLSE, which offers a way to deal with the critique by Pollak and Wales (1979) about "conditional" vs. "unconditional" equivalence scales. In Koulovatianos et al. (2005, p. 990) we have discussed that we do not expect our survey method to be influenced strongly by the conceptual distinction raised by Pollak and Wales (1979). The mild role played by the inclusion of NLSE in the regressions (see the quantitatively low NLSE coefficients in Table 1) reconfirms our earlier conjecture in Koulovatianos et al. (2005, p. 990).

standards of households with features different from their own. In order to enable tests of LIB that have sufficient statistical power, the sampling strategy should ensure that there are enough respondents who live in each of the household types that appear as hypothetical households in Part A.[28]

Let respondent i belong to household type h and let Y_i be the disposable household income of respondent i. From responses to Part A, we calculate five average EIs for household type h, each corresponding to an RI. We identify the average EI for household type h that is closest to Y_i. This identified average EI corresponds to an RI that should give the same level of material comfort for the one-member household. If this particular RI coincides with the RI that was randomly assigned to i in Part A, then i performed the MET for hypothetical households with material comforts close to his/her own. We use this identification procedure to create the dummy variables,

$LIB_{mc,i} = 1$ if respondent i's material comfort is closest to the material comfort of the one-member household, based on the RI that respondent i evaluated in Part A; 0 otherwise; and

$LIB_{h,i} = 1$ if respondent i belongs to household type h, and the dependent variable in the regression refers to household type h; 0 otherwise.

Variables $LIB_{h,i}$, $LIB_{mc,i}$, and the product $LIB_{h,i} \cdot LIB_{mc,i}$, serve as conditioning variables in the regression analysis of the stated EIs from Part A, and test for LIB.[29] A coefficient

---

[28]Since the RIs chosen in Part A cover a wide range of one-member-household disposable incomes, sampling should be such that, for each household type, the respondents' household income represents a wide range of the economy's household incomes.

[29]Table A4 in Appendix A shows the household-type distribution of respondents who are included in the $LIB_{mc,i}$ dummy variable. This is a total of 415 respondents, the sum of the entries in the first column of Table A4. Each entry in the first column of Table A4 shows the number of respondents in the $(LIB_{h,i} \cdot LIB_{mc,i})$ dummy variable for each household type. Apart from single-adult households with two or three children, LIB tests based on the $(LIB_{h,i} \cdot LIB_{mc,i})$ dummy variable have sufficient statistical power.

t-student test and a test of exclusion of each of these three variables test LIB. If none of b_2^h, b_3^h, and b_4^h, is significantly different from zero, then LIB does not prevent respondents from effectively performing the evaluation task of Part A. Table 1 shows that only two out of 21 dummy variables related to testing LIB are significant, but with small coefficients. Only one exclusion test is rejected (P<0.01) – for the household type with 2 adults and 1 child. These findings offer supporting evidence that respondents' own household type and/or level of material comfort do not bias their assessments of EIs in Part A.

$Personal\_Characteristics_i$: testing whether personal characteristics of respondents affect their answers. This is a set of conditioning variables referring to personal characteristics of the respondents. A coefficient t-student test and a test of exclusion of each of these variables indicate whether any characteristics of the respondents affect their assessments of EI. With two exceptions, Table 2 shows that respondents' personal characteristics do not appear statistically significant in the regressions. Respondents living in the New Laender report slightly higher ESs.[30] More educated respondents also state slightly higher ESs for hypothetical household types with children. Probably, more educated parents pursue higher education for their children. All significant coefficients are small.

Explanatory power of the regressions. The regressions fit the data quite well; they explain 30-54% of the total variation of stated ESs. Small standard errors for coefficients a^h and b^h in equation (18) indicate a broad consensus across respondents concerning the evaluation task of Part A.

Testing the affine relationship (16) using the six pilot surveys. As we discussed above, Figures 2 and 3 support the affine relationship given by (16) as well. Table 3 presents specification tests based on seemingly unrelated regressions (SUR) and the inclusion of dummies

---

[30]This is consistent with the findings by Alesina and Fuchs-Schündeln (2007) regarding differences in opinions between East Germans and West Germans.

around the linear functional form having the same structure as in the regression model (17).[31] With the highest value of the F-test statistic being 1.75, in all 42 cases examined the affine relationship given by (16) is not rejected.

4. Conclusion

A representative consumer is an artificial construct, a fictitious consumer whose choices always coincide with actual aggregated choices under any commodity prices. This idea links the behavior of the "small" (the household as a microeconomic unit) with the "large" (aggregated choices of households), motivating that the study of aggregate demanded quantities of a consumer basket reveals an accurate summary of incentives behind economic actions in the overall economy. Instilling the property of approximate aggregation in heterogeneous-agent models (see, for example, Krusell and Smith (1998)) by virtue of selecting particular functional forms for utility of households, rationalizes that agents can accurately understand information hidden in all complex aspects of an economy, by solely observing and predicting macroeconomic aggregates. In this paper we have focused on household-size heterogeneity, a real-life feature that raises the bar of difficulty for a representative consumer: individuals living in multi-member households benefit from sharing goods within the household, and this is a source of preference heterogeneity.

We demonstrated which family of utility functions is both necessary and sufficient for ensuring the existence of a representative consumer when decisions are made in a forward looking dynamic environment, when preferences differ across households, and also when preferences change over time. Our theoretical analysis led to an astonishingly simple result:

---

[31]Since for each family type the same respondent has provided five equivalent income evaluations, the error terms across the seven family types might be cross correlated. This can generate a loss in the efficiency of estimators and can weaken the confidence in our specification tests. To cope with this problem we estimate a system of 7 seemingly unrelated regressions.

once an economy is put in a steady state and households are given their permanent incomes, falsifying the whole theoretical construct of a representative consumer collapses into a single equation. What this equation says is that discretionary household incomes entail the same benefits from within-household sharing of goods across the rich and the poor. Through a survey instrument we have been able to create hypothetical household constructs that receive their permanent income as a flow and to test the empirical validity of this equation.

We have produced survey data from a large sample of respondents in Germany, both testing the critical equation for falsifying the representative consumer concept, and also demonstrating the effectiveness of our survey instrument. In seven tests the representative consumer has not been falsified, at least not with high confidence in marginal cases. In 42 more tests using pilot data from six countries the representative consumer construct has never been falsified. Although our results do not prove the existence of a representative consumer, they support the use of this concept as a workhorse in macroeconomics.

So, given our estimates from Table 1, and data taken from the German Income and Expenditure Survey in year 2003, the momentary utility function of the German representative consumer in 2003 is given by,

$$u^{RC}\left(c, t=2003\right) = \frac{\left(c + \frac{14.91}{\alpha} \cdot \beta_{OMH} - EUR\,3,281\right)^{1-\frac{1}{\alpha}} - 1}{1 - \frac{1}{\alpha}} \ , \tag{19}$$

where α is a free calibrating parameter, $-\beta_{OMH}/\alpha$ is the subsistence consumption of a one-member household, and the amount is in year 2003 Euros.[32]

---

[32]See Appendix D for the derivation of (19). In an aggregative model that uses the utility function given by (19), the appropriate measure of aggregate income to use is one-member-household equivalent income. In Appendix D we present how we construct the distribution of one-member-household equivalent incomes using data from the German Income and Expenditure Survey in year 2003.

5. Appendix − Proofs

Proof of Theorem 1

Part 1: Necessity

Fix any function $\rho : \mathbb{R}_+ \to \mathbb{R}_{++}$, and any collection $(u^i)_{i \in \mathcal{I}}$, with properties complying with Assumptions 1, 2, and 4. Assume that a representative consumer exists with some momentary utility function $v^{RC} : \mathbb{C}^{RC} \times \mathbb{R}_+ \to \mathbb{R}$, of the form $v^{RC}(c(t), t)$, at each point in time. Under Assumption 3, from Definition 1 and (5) it must be that,

$$\frac{v_1^{RC}\left(\int_{\mathcal{I}} c^i(t) \, d\mu(i), t\right)}{v_{11}^{RC}\left(\int_{\mathcal{I}} c^i(t) \, d\mu(i), t\right)} \left[r(t) + \frac{v_{12}^{RC}\left(\int_{\mathcal{I}} c^i(t) \, d\mu(i), t\right)}{v_1^{RC}\left(\int_{\mathcal{I}} c^i(t) \, d\mu(i), t\right)} \right] = \int_{\mathcal{I}} \mu(i) \frac{u_1^i(c^i(t))}{u_{11}^i(c^i(t))} di \left[r(t) - \rho(t) \right] , \tag{20}$$

where the term

$$-\frac{v_{12}^{RC}\left(\int_{\mathcal{I}} c^i(t) \, d\mu(i), t\right)}{v_1^{RC}\left(\int_{\mathcal{I}} c^i(t) \, d\mu(i), t\right)}$$

is the temporal rate of time preference of the representative consumer.

(Necessity) Step 1: preliminary characterization of the function $\int_0^\infty v^{RC}(c(t), t) \, dt$.

According to Definition 1, the existence (and the implied preference primitives) of the representative consumer should be independent from any price regime. The case where $r(t) = \rho(t)$ for all $t \geq 0$, should always be included in the price domain. To see this, fix any moment in time, $t \in \mathbb{R}_+$, pick any household $i \in \mathcal{I}$, and multiply her budget constraint, (3), by the integrating factor $e^{-\int_t^\tau r(s)ds}$, integrate over all $\tau \in [t, \infty)$, and apply the transversality condition, to obtain,

$$\int_t^\infty e^{-\int_t^\tau r(s)ds} c^i(t) \, d\tau = a^i(t) + \int_t^\infty e^{-\int_t^\tau r(s)ds} \theta^i(\tau) w(\tau) \, d\tau . \tag{21}$$

For the case $r(t) = \rho(t)$ for all $t \geq 0$, under Assumption 3, (5) implies that $\dot{c}^i(t) = 0$ for all $t \in \mathbb{R}_+$, and all $i \in \mathcal{I}$, so, (21) implies that

$$c^i(t) = \hat{c}^i = \frac{a^i(t) + \int_t^\infty e^{-\int_t^\tau \rho(s)ds} \theta^i(\tau) w(\tau) d\tau}{\int_t^\infty e^{-\int_t^\tau \rho(s)ds} d\tau} \ , \quad \text{for all } t \geq 0. \tag{22}$$

For the given preference profile, $(u^i)_{i \in \mathcal{I}}$, (22) implies that there are always $(a_0^i, \theta^i)_{i \in \mathcal{I}}$ and $(w(t))_{t \geq 0}$ securing that $\hat{c}^i \in \mathbb{C}^i$ for all $i \in \mathcal{I}$, and for all $t \geq 0$. So, the case $r(t) = \rho(t)$ for all $t \geq 0$, is always part of the domain complying with Assumption 3, for any $(u^i)_{i \in \mathcal{I}}$ that satisfies Assumptions 1, 2, and 4.

Thus, set $r(t) = \rho(t)$ for all $t \geq 0$ and pick an appropriate $(a_0^i, \theta^i)_{i \in \mathcal{I}}$ and $(w(t))_{t \geq 0}$ securing that $\hat{c}^i > \underline{c}^i$ for all $i \in \mathcal{I}$, and for all $t \geq 0$, and also set,

$$c \equiv \int_{\mathcal{I}} \hat{c}^i d\mu(i) \ .$$

Equations (20) and (22) imply that the necessary optimality conditions of the representative consumer are,

$$-\frac{v_{12}^{RC}(c,t)}{v_1^{RC}(c,t)} = \rho(t) \ .$$

So, standard Riemann integration with respect to t over the time interval $[0,t]$ implies that,

$$v_1^{RC}(c,t) = e^{-\int_0^t \rho(\tau)d\tau} v_1^{RC}(c,0) \ ,$$

or,

$$v^{RC}(c,t) = e^{-\int_0^t \rho(\tau)d\tau} v^{RC}(c,0) \ ,$$

ignoring the constant, since this is a utility function. Setting,

$$u^{RC}(c) \equiv v^{RC}(c,0) \ ,$$

we conclude that the objective of the representative consumer must be of the form,

$$U^{RC}\left((c(t))_{t \geq 0}\right) = \int_0^\infty e^{-\int_0^t \rho(\tau)d\tau} u^{RC}(c(t)) dt \ . \tag{23}$$

For notational ease, let $f^{RC} : \mathbb{C}^{RC} \to \mathbb{R}_{++}$ and $(f^i : \mathbb{C}^i \to \mathbb{R}_{++})_{i \in \mathcal{I}}$, with

$$
f^{RC}(\cdot) = -\frac{v_1^{RC}(\cdot)}{v_{11}^{RC}(\cdot)} \qquad \text{and} \qquad f^i(\cdot) = -\frac{u_1^i(\cdot)}{u_{11}^i(\cdot)} \quad \text{for all } i \in \mathcal{I}.
$$

Combining (23) with (20), it is,

$$
f^{RC}\left(\int_{\mathcal{I}} c^i(t)\, d\mu(i)\right) = \int_{\mathcal{I}} f^i\left(c^i(t)\right) d\mu(i) \ , \tag{24}
$$

for all $(c^i(t) \in \mathbb{C}^i)_{i \in \mathcal{I}}$ that are consumer-equilibrium choices and $t \geq 0$.

(Necessity) Step 2: characterization of $f^{RC} : \mathbb{R}_+ \to \mathbb{R}_{++}$ and $(f^i : \mathbb{R}_+ \to \mathbb{R}_{++})_{i \in \mathcal{I}}$. In this step we show that,

$$
(24) \Leftrightarrow \left\{ \begin{array}{c} f^i(c) = \alpha c + \beta_i \ , \quad \text{and,} \\[2mm] f^{RC}(c) = \alpha c + \int_{\mathcal{I}} \beta_i d\mu(i) \ , \\[2mm] \text{for some } \alpha \in \mathbb{R} \text{ and some } \beta_i \in \mathbb{R}, \text{ for all } i \in \mathcal{I} \end{array} \right\} . \tag{25}
$$

The sufficiency part of (25) is straightforward. For the necessity part of (25), let (24) hold, being the only information available concerning $f^{RC} : \mathbb{R}_+ \to \mathbb{R}_{++}$ and the collection $(f^i : \mathbb{R}_+ \to \mathbb{R}_{++})_{i \in \mathcal{I}}$. Suppose that $r(t) = \rho(t)$ for all $t \geq 0$, and, given (22), find a common distribution of $(a_0^i, \theta^i)_{i \in \mathcal{I}}$ and $(w(t))_{t \geq 0}$, where $a_0^i = a_0$ and $\theta^i = \theta$, so that $c^i(t) = \tilde{c}$ for all $i \in \mathcal{I}$, and all $t \geq 0$, also with $\tilde{c} \in \underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i$.

Let,

$$
\Phi^{RC}(c) \equiv f^{RC}(c) - f^{RC}(\tilde{c}) \ , \tag{26}
$$

and,

$$\Phi^i (c) \equiv f^i (c) - f^i (\tilde{c}) \ , \quad \text{for all } i \in \mathcal{I} \ . \tag{27}$$

For this distribution, (24) implies that,

$$f^{RC} (\tilde{c}) = \int_{\mathcal{I}} f^i (\tilde{c}) \, d\mu (i) \ . \tag{28}$$

Given (1), set $\underline{\mu}$ such that,

$$0 < \underline{\mu} \leq \inf \{ d\mu (i) \mid i \in \mathcal{I} \} \ . \tag{29}$$

Pick any arbitrary household type $i \in \mathcal{I}$, keep prices as before, and modify the previous distribution by adding to $\underline{\mu}$ of this household type different wealth or productivity that yields $c^i (t) = (\tilde{c} + \Delta c) \in \underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i$, for all $t \geq 0$. Since prices are the same, $c^j (t) = \tilde{c}$, for all $j \in \mathcal{I} \backslash \{i\}$ and for some households of type i with density $d\mu (i) - \underline{\mu}$, and for all $t \geq 0$. Combining (24), (28), (26) and (27), it is,

$$\Phi^{RC} \left(\underline{\mu} \Delta c + \tilde{c} \right) = \underline{\mu} \Phi^i \left(\Delta c + \tilde{c} \right) \ . \tag{30}$$

Since the choices of $i \in \mathcal{I}$, Δc, and $\tilde{c} \in \underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i$, were arbitrary, and since we can construct the same distribution of consumption choices for all $i \in \mathcal{I}$, (30) holds for all $i \in \mathcal{I}$, so,

$$\Phi^i (c) = \Phi (c) \quad \text{for all } c \in \underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i \text{ and for all } i \in \mathcal{I}. \tag{31}$$

Given (22), we are able to construct any interior optimal path with distribution of consumptions with $c^i (t) = c \in \underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i$ for all $i \in \mathcal{I}$, and all $t \geq 0$. Therefore, (24), (28), and (31) imply that,

$$\Phi^{RC} (c) = \Phi^i (c) = \Phi (c) \quad \text{for all } c \in \underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i \text{ and for all } i \in \mathcal{I} \ , \tag{32}$$

and,

$$\Phi \left(\int_{\mathcal{I}} c^i (t) \, d\mu (i) \right) = \int_{\mathcal{I}} \Phi \left(c^i (t) \right) d\mu (i) \ , \quad \text{for all } \left(c^i (t) \in \underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i \right)_{i \in \mathcal{I}}, \text{ and } t \geq 0 \ , \tag{33}$$

holding for the whole domain of wealth/labor-productivity heterogeneity and prices where household choices fall in the interval $\underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i$ (see Assumption 4) and are interior. Equation (33) enables us to further characterize Φ. In particular,

$$(33) \Leftrightarrow \Phi \text{ is affine on } \underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i. \tag{34}$$

The sufficiency part of (34) is straightforward, so for the necessity part of (34) let's set,

$$z^i \equiv c^i - \tilde{c} , \tag{35}$$

with $\tilde{c}$ defined as above for an arbitrary $\tilde{c} \in \underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i$, in the case where $r(t) = \rho(t)$ for all $t \geq 0$. So, fix $\tilde{c}$ and set,

$$\Psi(z) \equiv \Phi(z) - \Phi(0) , \tag{36}$$

since we know that for the transformed variable, z, the choice of 0 falls in the class of interior solutions to a distribution in the domain of $(u^i)_{i \in \mathcal{I}}$, namely the case where all households choose $\tilde{c} \in \underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i$ at all times. We now show that Ψ is a linear functional. For any partition of households, irrespective of their household types, say, $\mathcal{I}_1, \mathcal{I}_2 \subset \mathcal{I}$, with $\mathcal{I}_1 \cap \mathcal{I}_2 = \emptyset$, and $\int_{\mathcal{I}_1} d\mu(i) = \mu$, retaining $r(t) = \rho(t)$ for all $t \geq 0$, provide the same a_0 and a labor-productivity function θ to all $i \in \mathcal{I}_1$, so that consumption is equal to $(\Delta c + \tilde{c}) \in \underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i$ for all $i \in \mathcal{I}_1$ at all times, provide to the remaining households $\tilde{a}_0$ and a labor-productivity $\tilde{\theta}$, so that their consumption is equal to $\tilde{c} \in \underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i$ for all $i \in \mathcal{I}_2$ at all times. Then, $z^i = \Delta c$ for all $i \in \mathcal{I}_1$, and $z^i = 0$ for all $i \in \mathcal{I}_2$, so,

$$\Phi(\mu \Delta c) = \Phi(\mu \Delta c + (1 - \mu) 0) ,$$

and (33) and (36) imply that,

$$\Phi(\mu \Delta c) = \mu \Phi(\Delta c) + (1 - \mu) \Phi(0) ,$$

or,

$$\Psi(\mu \Delta c) = \mu \Psi(\Delta c) \ . \tag{37}$$

Notice that the choices of Δc and μ were arbitrary. So, we can take any $\mu_1, \mu_2 \in (0,1)$ with $(\mu_1 \Delta c + \tilde{c}), (\mu_1 \Delta c + \tilde{c}) \in \underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i$ and $\frac{\mu_2}{\mu_1} = \xi \in \mathbb{R}_+$. Repeating the same steps, (37) yields $\Psi(\mu_1 \Delta c) = \mu_1 \Psi(\Delta c)$ and $\Psi(\xi \mu_1 \Delta c) = \xi \mu_1 \Psi(\Delta c)$, or,

$$\Psi(\xi \mu_1 \Delta c) = \xi \Psi(\mu_1 \Delta c), \quad \text{for all } \xi \in \mathbb{R}_+ \ . \tag{38}$$

Since Ψ is a univariate function, (38) is sufficient to prove that Ψ is linear. So, let,

$$\Psi(z) = \alpha z \ , \quad \alpha \in \mathbb{R},$$

and, due to the linearity of Ψ, the transformation (35) can be ignored, having (36) and (32) implying that, $\Phi(c) = \alpha c + \Phi(0)$. But since (26) and (27) imply that $\Phi(\tilde{c}) = 0$, $\Phi(0) = -\alpha \tilde{c}$. So,

$$\Phi^{RC}(c) = \Phi^i(c) = \Phi(c) = \alpha c - \alpha \tilde{c} \ , \quad \alpha \in \mathbb{R}, \text{ for all } c \in \underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i \text{ and for all } i \in \mathcal{I} \ . \tag{39}$$

Using (39) we show that,

$$\Phi^i(c) = \Phi(c) = \alpha c - \alpha \tilde{c} \ , \quad \alpha \in \mathbb{R}, \text{ for all } c \in \mathbb{C}^i \text{ and for all } i \in \mathcal{I} \ . \tag{40}$$

To prove (40), consider the case where an arbitrary $c^j \in \mathbb{C}^j$ is such that $c^j \leq \inf \left(\underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i \right)$ or $c^j \geq \sup \left(\underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i \right)$ for some $j \in \mathcal{I}$, whenever any of the two is possible (i.e. whenever $\inf \left(\underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i \right) > 0$, or $\sup \left(\underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i \right) < \infty$). It is always that there exists some $\mu \in (0,1)$, with $\mu \leq d\mu(j)$, such that $(\mu c^j + (1-\mu)\tilde{c}) \in \underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i$. So, retaining $r(t) = \rho(t)$ for all $t \geq 0$, provide a level a_0 and a labor-productivity function θ to a mass μ of type $j \in \mathcal{I}$, so that consumption is equal to c^j at all times, and also provide to the remaining households $\tilde{a}_0$

and a labor-productivity $\tilde{\theta}$, so that their consumption is equal to $\tilde{c} \in \underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i$ at all times. Combining (24), (26), (27) and (28), it is,

$$\mu \Phi^j \left(c^j \right) = \Phi^{RC} \left(\mu c^j + (1 - \mu) \tilde{c} \right) \ .$$

But since $\left(\mu c^j + (1 - \mu) \tilde{c} \right) \in \underset{i \in \mathcal{I}}{\cap} \mathbb{C}^i$, (39) implies that $\Phi^{RC} \left(\mu c^j + (1 - \mu) \tilde{c} \right) = \alpha \left(\mu c^j + (1 - \mu) \tilde{c} \right) - \alpha \tilde{c}$, or

$$\Phi^j \left(c^j \right) = \alpha c^j - \alpha \tilde{c} \ .$$

Since the choices of $j \in \mathcal{I}$ and $c^j \in \mathbb{C}^j$ were arbitrary, (40) is proved.

Combining (27) with (40) it is,

$$f^i \left(c \right) = \alpha c - \alpha \tilde{c} + f^i \left(\tilde{c} \right) \quad \text{for all } c \in \mathbb{C}^i \text{ and all } i \in \mathcal{I} \ . \tag{41}$$

Now that all f^i's are completely characterized over their domains, $\mathbb{C}^i$, we can consider the case of $c = 0$, irrespective from whether $0 \in \mathbb{C}^i$ or not, in order to set the intercepts of all f^i's. Equation (41) implies,

$$f^i \left(\tilde{c} \right) = \alpha \tilde{c} + f^i \left(0 \right) \ . \tag{42}$$

Setting $f^i \left(0 \right) = \beta_i$ for some $\beta_i \in \mathbb{R}$, for all $i \in \mathcal{I}$, a final combination of (41) with (42), and also setting $\beta_{RC} = \int_{\mathcal{I}} \beta_i d\mu \left(i \right)$ (consistently with (24)), completes the proof of (25).

(Necessity) Step 3: characterization of $\left(u^i : \mathbb{R}_+ \to \mathbb{R} \right)_{i \in \mathcal{I}}$ *and* $u^{RC} : \mathbb{R}_+ \to \mathbb{R}$.

In light of (25), we derive the functional forms of utility for all household types through Riemann integration. There are two general cases, these of $\alpha \neq 0$ and $\alpha = 0$. (The case where $\alpha = 1$ is also of special interest, but the particular functional form of $\left(u^i \right)_{i \in \mathcal{I}}$ and u^{RC} that result in this case, can be derived from the more general functional forms that apply to $\alpha \neq 0$.)

For the case where $\alpha \neq 0$, (25) implies that,

$$\frac{u_{11}^i(c)}{u_1^i(c)} = -\frac{1}{\alpha c + \beta_i} \ , \tag{43}$$

and the indefinite Riemann integral of this expression with respect to c yields,

$$\ln\left[u_1^i(c)\right] = -\frac{1}{\alpha}\ln\left(\alpha c + \beta_i\right) + \kappa_i \ , \tag{44}$$

where κ_i is some constant in $\mathbb{R}$, that can be household-specific, and integrating once more,

it is,

$$u^i(c) = e^{\kappa_i}\frac{\left(\alpha c + \beta_i\right)^{1-\frac{1}{\alpha}}}{\alpha\left(1 - \frac{1}{\alpha}\right)} + \kappa \ , \tag{45}$$

where κ is, again some constant. Setting $e^{\kappa_i} = 1$, without loss of generality, and κ accordingly, we obtain the result of (8). The special case where $\alpha = 1$, is known to yield the result that $u^i(c) = \ln\left(\alpha c + \beta_i\right) + \kappa$, through computing the limit of the above expression for $\alpha \to 1$ using L'Hôpital's rule. The preferences of the representative consumer are derived in the same way.

For the case where $\alpha = 0$,

$$\frac{u_{11}^i(c)}{u_1^i(c)} = -\frac{1}{\beta_i} \ , \tag{46}$$

and in order for $u_1^i > 0$ and $u_{11}^i < 0$ to hold, it must be that $\beta_i > 0$. So,

$$\ln\left[u_1^i(c)\right] = -\frac{1}{\beta_i}c + \kappa_i \ , \tag{47}$$

and,

$$u^i(c) = -\frac{e^{\kappa_i}}{\beta_i}e^{-\frac{1}{\beta_i}c} + \kappa \ , \tag{48}$$

so, setting $\frac{e^{\kappa_i}}{\beta_i} = 1$ and $\kappa = 0$ yields the corresponding function in (8). With the same reasoning for the representative consumer, the proof of the necessity part is complete.

Part 2: Sufficiency

The particular functional forms given by (8) enable a complete analytical characterization of the demand functions of all households at all times. Again, two cases must be examined separately, this of $\alpha \neq 0$ and the case where $\alpha = 0$.

Under the assumption that $\alpha \neq 0$, (5), implies,

$$\ddot{c}^i(t) = \left[\alpha c^i(t) + \beta_i\right]\left[r(t) - \rho(t)\right] ,$$

so, multiplying this expression by the integrating factor $e^{-\alpha \int_t^\tau [r(s) - \rho(s)]ds}$ and integrating over the interval $[t, \tau]$ for any $\tau \in [t, \infty)$, yields,

$$c^i(\tau) = c^i(t) e^{\alpha \int_t^\tau [r(s) - \rho(s)]ds} + \beta_i e^{\alpha \int_t^\tau [r(s) - \rho(s)]ds} \int_t^\tau e^{-\alpha \int_t^\tau [r(s) - \rho(s)]ds} \left[r(s) - \rho(s)\right] ds .$$

Multiplying this last expression by $e^{-\int_t^\tau r(s)ds}$, integrating over all $\tau \in [t, \infty)$, and combining the result with (21), gives,

$$c^i(t) = \frac{a^i(t) + \int_t^\infty e^{-\int_t^\tau r(s)ds}\theta^i(\tau) w(\tau) d\tau}{\int_t^\infty e^{\int_t^\tau [(\alpha-1)r(s) - \alpha\rho(s)]ds} d\tau} -$$

$$- \frac{\beta_i \int_t^\infty e^{\int_t^\tau [(\alpha-1)r(s) - \alpha\rho(s)]ds} \int_t^\tau e^{-\alpha \int_t^\tau [r(s) - \rho(s)]ds} \left[r(s) - \rho(s)\right] ds d\tau}{\int_t^\infty e^{\int_t^\tau [(\alpha-1)r(s) - \alpha\rho(s)]ds} d\tau} , \quad (49)$$

which can be linearly aggregated across all a^i's, θ^i's and β_i's, proving that a representative consumer exists, as long as Assumption 1 holds, which keeps all individual demands taking the form of (49).

For the case where $\alpha = 0$, when all individual utilities fall in the class of $u^i(c) = -e^{-\frac{1}{\beta_i}c}$, (49) implies that,

$$c^i(t) = \frac{a^i(t) + \int_t^\infty e^{-\int_t^\tau r(s)ds}\theta^i(\tau) w(\tau) d\tau - \beta_i \int_t^\infty e^{-\int_t^\tau r(s)ds} \int_t^\tau \left[r(s) - \rho(s)\right] ds d\tau}{\int_t^\infty e^{-\int_t^\tau r(s)ds} d\tau} , \quad (50)$$

which can also be linearly aggregated across all a^i's, θ^i's and β_i's, completing the proof of the theorem. *Q.E.D.*

Proof of Theorem 2

Part 1: Necessity

Fix any function $\rho : \mathbb{R}_+ \to \mathbb{R}_{++}$, and any collection $(u^i)_{i \in \mathcal{I}}$, with properties complying with Assumptions 2, 3, and 5 through 7. Assume that a representative consumer exists with some momentary utility function $v^{RC} : \mathbb{C}^{RC} \times \mathbb{R}_+ \to \mathbb{R}$, of the form $v^{RC}(c(t), t)$, at each point in time.

Considering any $i \in \mathcal{I}$, its optimality conditions imply that,

$$-\frac{u_{11}^i\left(c^i(t), t\right)}{u_1^i\left(c^i(t), t\right)}\dot{c}^i(t) - \frac{u_{12}^i\left(c^i(t), t\right)}{u_1^i\left(c^i(t), t\right)} = r(t) - \rho(t) , \quad t \geq 0 . \tag{51}$$

Now pick $r(t) = \rho(t)$ for all $t \geq 0$, substitute it to (51) and take the indefinite integral with respect to time to get,

$$u_1^i\left(c^i(t), t\right) = \kappa , \quad t \geq 0 . \tag{52}$$

where κ is some constant. Due to the fact that $u_{11}^i\left(c^i(t), t\right) < 0$, and due to Assumptions 6 and 7, there is always a $\kappa > 0$ such that $c^i(t) \in \mathbb{C}^i(t)$ for all $t \geq 0$, satisfying (52). For $r(t) = \rho(t)$, (51) implies that,

$$\dot{c}^i(t) = -\frac{u_{12}^i\left(c^i(t), t\right)}{u_{11}^i\left(c^i(t), t\right)} . \tag{53}$$

The level of κ in (52) will be uniquely identified by setting $u_1^i\left(c^i(0), 0\right) = \kappa$ and applying (21) at time 0, combined with the dynamics of $c^i(t)$ implied by (53). Due to Assumption 6, such an interior path exists on $\mathfrak{C}^i$, as $\mathfrak{C}^i$ is defined in Assumption 7. This means that with the right choices of initial wealth and labor productivity, we can construct interior paths that span $\mathfrak{C}^i$. Moreover, always for the case where $r(t) = \rho(t)$ for all $t \geq 0$, due to Assumption 7, for any $i \in \mathcal{I}$, we can generate any choice of $c \in \bigcap_{i \in \mathcal{I}} \mathfrak{C}^i$ at any point in time, picking the appropriate initial wealth and labor productivity, since the dynamics of consumption are solely driven by (53).

With this facility at hand, we can look at the problem of the representative consumer, whose optimal Euler equation gives,

$$-\frac{v_{11}^{RC}\left(\int_{\mathcal{I}}c^i\left(t\right)d\mu\left(i\right),t\right)}{v_1^{RC}\left(\int_{\mathcal{I}}c^i\left(t\right)d\mu\left(i\right),t\right)}\int_{\mathcal{I}}\dot{c}^i\left(t\right)d\mu\left(i\right)-\frac{v_{12}^{RC}\left(\int_{\mathcal{I}}c^i\left(t\right)d\mu\left(i\right),t\right)}{v_1^{RC}\left(\int_{\mathcal{I}}c^i\left(t\right)d\mu\left(i\right),t\right)}=r\left(t\right)\ ,\quad t\geq 0\ ,\qquad (54)$$

and combining it with (51), it is,

$$\frac{v_1^{RC}\left(\int_{\mathcal{I}}c^i\left(t\right)d\mu\left(i\right),t\right)}{v_{11}^{RC}\left(\int_{\mathcal{I}}c^i\left(t\right)d\mu\left(i\right),t\right)}r\left(t\right)+\frac{v_{12}^{RC}\left(\int_{\mathcal{I}}c^i\left(t\right)d\mu\left(i\right),t\right)}{v_1^{RC}\left(\int_{\mathcal{I}}c^i\left(t\right)d\mu\left(i\right),t\right)}=$$

$$=\left[r\left(t\right)-\rho\left(t\right)\right]\int_{\mathcal{I}}\frac{u_1^i\left(c^i\left(t\right),t\right)}{u_{11}^i\left(c^i\left(t\right),t\right)}d\mu\left(i\right)+\int_{\mathcal{I}}\frac{u_{12}^i\left(c^i\left(t\right),t\right)}{u_{11}^i\left(c^i\left(t\right),t\right)}d\mu\left(i\right)\ .\qquad (55)$$

Setting $r\left(t\right)=\rho\left(t\right)$ for all $t\geq 0$, (55) becomes,

$$\frac{v_1^{RC}\left(\int_{\mathcal{I}}c^i\left(t\right)d\mu\left(i\right),t\right)}{v_{11}^{RC}\left(\int_{\mathcal{I}}c^i\left(t\right)d\mu\left(i\right),t\right)}\rho\left(t\right)+\frac{v_{12}^{RC}\left(\int_{\mathcal{I}}c^i\left(t\right)d\mu\left(i\right),t\right)}{v_1^{RC}\left(\int_{\mathcal{I}}c^i\left(t\right)d\mu\left(i\right),t\right)}=\int_{i\in\mathcal{I}}\frac{u_{12}^i\left(c^i\left(t\right),t\right)}{u_{11}^i\left(c^i\left(t\right),t\right)}d\mu\left(i\right)\ .\qquad (56)$$

But since, as explained above, for the case where $r\left(t\right)=\rho\left(t\right)$ for all $t\geq 0$, one can generate any distribution of consumption choices, (56) holds for the whole domain implied by Assumption 3. So, substituting (56) into (55), it is,

$$\frac{v_1^{RC}\left(\int_{\mathcal{I}}c^i\left(t\right)d\mu\left(i\right),t\right)}{v_{11}^{RC}\left(\int_{\mathcal{I}}c^i\left(t\right)d\mu\left(i\right),t\right)}=\int_{i\in\mathcal{I}}\frac{u_1^i\left(c^i\left(t\right),t\right)}{u_{11}^i\left(c^i\left(t\right),t\right)}d\mu\left(i\right)\ ,\qquad (57)$$

for the whole domain implied by Assumption 3, including the case where $r\left(t\right)=\rho\left(t\right)$ for all $t\geq 0$. But then, for any $t\geq 0$, the same argument that was developed in step 2 of the necessity part of the proof of Theorem 1, to get,

$$\frac{u_1^i(c,t)}{u_{11}^i(c,t)}=\alpha\left(t\right)c+\beta^i\left(t\right)\ ,\quad\text{and,}$$

$$\frac{v_1^{RC}(c,t)}{v_{11}^{RC}(c,t)}=\alpha\left(t\right)c+\int_{\mathcal{I}}\beta^i\left(t\right)d\mu\left(i\right)\ ,\qquad (58)$$

for some $\alpha\left(t\right)\in\mathbb{R}$ and some $\beta^i\left(t\right)\in\mathbb{R}$, for all $i\in\mathcal{I}$, $t\geq 0$

Using (58), with the same procedure as in step 3 of the necessity part of Theorem 1, candidate utility functions arise. Deriving individual demands, one can verify that this is possible only if

$$\alpha\left(t\right)=\alpha\neq 0\ ,\text{ and }\beta^i\left(t\right)\text{ meeting Assumptions 6, 7, }t\geq 0\ ,$$

and

$$\alpha = 0, \quad \beta^i(t) = \beta_i G(t) \ ,$$

that match the utility functions of the theorem. In particular, for the case where $\alpha \neq 0$, demands are,

$$c^i(t) = \frac{a^i(t) + \int_t^\infty e^{-\int_t^\tau r(s)ds} \theta^i(\tau) w(\tau) d\tau + \frac{1}{\alpha} \int_t^\infty e^{\int_t^\tau [(\alpha-1)r(s) - \alpha\rho(s)]ds} \beta^i(\tau) d\tau}{\int_t^\infty e^{\int_t^\tau [(\alpha-1)r(s) - \alpha\rho(s)]ds} d\tau} - \frac{\beta^i(t)}{\alpha} \ ,$$

(59)

which are linear with respect to β^i's. On the contrary, the demands for the utility function,

$$u^i(c,t) = -e^{-\frac{1}{\beta^i(t)} c} \ ,$$

are,

$$c^i(t) = \frac{a^i(t) + \int_t^\infty e^{-\int_t^\tau r(s)ds} \theta^i(\tau) w(\tau) d\tau - \int_t^\infty e^{-\int_t^\tau r(s)ds} \beta^i(\tau) \int_t^\tau [r(s) - \rho(s)] ds d\tau}{\int_t^\infty e^{-\int_t^\tau r(s)ds} \frac{\beta^i(\tau)}{\beta^i(t)} d\tau} \ ,$$

(60)

which can be linearly aggregated only if $\frac{\beta^i(t)}{\beta^i(0)} = \frac{\beta^j(t)}{\beta^j(0)}$ for all $i,j \in \mathcal{I}$, i.e. only when $\beta^i(t) = \beta_i G(t)$, $\beta_i > 0$ for all $i \in \mathcal{I}$, completing the necessity part.

Part 2: Sufficiency

Follows by (59) and (60), observing that, under the statement of the theorem, they are linear with respect to a^i's, θ^i's and β^i's. *Q.E.D.*

Proof of Proposition 1

Suppose that a representative consumer exists, which gives rise to a preference profile $(u^i)_{i \in \mathcal{I}}$ characterized by (25) that appears in the proof of Theorem 1.

In the case where $\alpha = 0$, equation (25) implies equation (46) which can be integrated with respect to c to yield equations (47) and (48). Under all assumptions made in the statement of Proposition 1, equation (15) holds for all $i, j \in \mathcal{I}$, but for the empirical identification of any pair $\left(\bar{y}_E^i, \bar{y}_E^j \right)$, $i, j \in \mathcal{I}$ (for avoiding indeterminacy), constants added to the functional form (48) cannot be different across any two $i, j \in \mathcal{I}$. On the contrary, parameter κ_i in (48) can differ across $i, j \in \mathcal{I}$, since κ_i determines the level of i's marginal utility of consumption in relation to the marginal utility of all other household types. So, combining equations (15) and (47) implies

$$\bar{y}_E^j = \beta_j \left(\kappa_j - \kappa_i \right) + \frac{\beta_j}{\beta_i} \bar{y}_E^i \ ,$$

which is consistent with (16).

In the case where $\alpha \neq 0$, and $\alpha \neq 1$, from the proof of Theorem 1 we can see that equation (45) holds, under the constraint that constants added to the functional form (45) cannot be different across any two $i, j \in \mathcal{I}$, for enabling the empirical identification of any pair $\left(\bar{y}_E^i, \bar{y}_E^j \right)$, $i, j \in \mathcal{I}$, while parameter κ_i can differ across $i, j \in \mathcal{I}$, $i \neq j$. Equations (15) and (45) imply,

$$\bar{y}_E^j = \frac{e^{\frac{\alpha}{\alpha-1}(\kappa_i - \kappa_j)} \beta_i - \beta_j}{\alpha} + e^{\frac{\alpha}{\alpha-1}(\kappa_i - \kappa_j)} \bar{y}_E^i \ , \tag{61}$$

which is also consistent with (16).

For the case where $\alpha = 1$, the existence of a representative consumer and empirical identification of any pair $\left(\bar{y}_E^i, \bar{y}_E^j \right)$, $i, j \in \mathcal{I}$, imply that $\kappa_i = \kappa_j = 0$ for all $i, j \in \mathcal{I}$. To see this, suppose, that, to the contrary, for some $i, j \in \mathcal{I}$, $i \neq j$, it is $\kappa_i \neq \kappa_j$ and also $\kappa_i \neq 0$,

without loss of generality. Then equation (44) implies, after setting $\alpha = 1$, that

$$u_1^i(c) = \frac{e^{\kappa_i}}{c + \beta_i} \ . \tag{62}$$

Integrating (62) with respect to c yields,

$$u^i(c) = e^{\kappa_i} \ln(c + \beta_i) + b \ , \tag{63}$$

where b is some constant which is common across all household types. Alternatively, (62) can be re-written as

$$u_1^i(c) = \frac{1}{e^{-\kappa_i} c + e^{-\kappa_i} \beta_i} \ ,$$

and integrating this last equation with respect to c gives,

$$u^i(c) = e^{\kappa_i} \left[\ln(c + \beta_i) - \kappa_i \right] + b \ . \tag{64}$$

Comparing (63) with (64) implies that the constant b must be adjusted for $i \in \mathcal{I}$, which contradicts the requirement that any pair $\left(\bar{y}_E^i, \bar{y}_E^j \right)$, $i, j \in \mathcal{I}$, can be uniquely identified by data by not allowing household-type specific constants to be added to utility functions. So, the only way that (63) and (64) coincide is setting $\kappa_i = 0$. Due to the arbitrary choice of i, it is $\kappa_i = \kappa_j = 0$ for all $i, j \in \mathcal{I}$, and (15) implies

$$\bar{y}_E^j = \beta_i - \beta_j + \bar{y}_E^i \ , \tag{65}$$

which is the special case of (61) with $\kappa_i = \kappa_j = 0$ for all $i, j \in \mathcal{I}$ and with $\alpha = 1$. In fact, setting $\alpha = 1$ in (61) directly implies that it can only be $\kappa_i = \kappa_j = 0$ for all $i, j \in \mathcal{I}$. Since (65) is also consistent with (16), the proposition is proved. Q.E.D.

1. Appendix A – Representative Research Sample in Germany: Calibration of Main Evaluation Task and Sampling

In order to implement Part A of the questionnaire efficiently, it is necessary to examine demographic and descriptive income statistics from the country being studied in order to determine appropriate household types and reference incomes (RIs) to use in Part A. In Germany, the eight household types that were chosen represent 86.05% of the overall number of households, as seen in Table A1, based on the most recent German Income and Expenditure Survey (EVS) of 2003.[1] The EVS, provided by the German Statistical Office in five-year intervals, contains representative household-level information on income, wealth, and expenditures for several types of goods. The RIs provided in Part A were determined so as to cover a broad range of the disposable-income distribution for single-childless-adult households in Germany. The amount of EUR 500 per month is the level of total social assistance for a one-member household in Germany. Specifically, the level of monetary social assistance in 2006 for a single, childless adult is EUR 345 per month (see Article 20, Paragraph 2, 2a, 3, Sozialgesetzbuch II (SGB II - "Social Security Code")).[2] In addition, households receive housing allowances. The level of housing allowances is contingent upon the rent and also upon the income and wealth of the single, childless adult. A reasonable number is ca. EUR 160. The amount of EUR 1,250 corresponds to the 41st percentile of the one-member-household monthly disposable-income distribution, EUR 2,000 to the 76th, EUR 2,750 to the 89th, and EUR 3,500 to the 94th percentile. Each respondent was provided with only one RI to evaluate in Part A (by random assignment).

---

[1] See the German Social Science Infrastructure Services at:
http://www.gesis.org/en/social_monitoring/GML/data/inc&exp/index.htm.
[2] For the German Social Security Code see, http://www.sozialgesetzbuch-bundessozialhilfegesetz.de/_buch/sgb_ii.htm.

The survey's sample consists of 2,042 respondents from all regions of Germany, collected by the research institute "FORSA" ("Gesellschaft für Sozialforschung und statistische Analysen mbH" - Research Institute for Social Research and Statistical Analyses) in 2006. The FORSA institute routinely conducts surveys with a representative online panel of about 10,000 German households. FORSA has stored an extensive set of socioeconomic and demographic variables for each participating household. This enables a pre-screening of respondents' personal and household characteristics. Households were provided with web TVs when internet was not available. Completion times ranged from about 10 to 25 minutes.

The sampling procedure is targeted to obtain enough respondents who live in each of the household types that appear as hypothetical households in Part A. Table A2 shows the breakdown of the large sample from Germany, and Table A3 shows the number of respondents from each family type. Table A3 also compares the percentages of respondents from each household type in the sample with the percentages of household types in the overall German population. This comparison reveals that pre-screening of respondent characteristics is efficient. The household type consisting of 1 adult with 3 children has been more than six times over-represented in the sample compared to the German population. Even so, there were only 19 respondents from households with 1 adult and 3 children. For the other seven household types, respondent numbers are sufficiently high to conduct the tests explained below.

2. Appendix B – Pilot Survey Samples

The breakdown of the samples in pilot studies appears in Tables B1a and B1b. The complete questionnaire appears in Appendix A.1 of Koulovatianos et al. (2005). In Botswana the questionnaire consisted of questions about three reference incomes instead of five. Be-

cause several languages (mainly Setswana and Kalanga, but also Sekgalagadi) are used in Botswana, interviewers had to resort to oral interviews. The response rate with five reference incomes was low and given our planned budget and time constraints we modified the questionnaire so as to increase the response rate. For the purpose of testing the income dependence of equivalence scales three reference incomes serve this task well. For testing the linear relationship between EIs and RIs, three reference incomes are marginally sufficient for such a test. Nevertheless, we include this country in this study as complementary information.

The questionnaire, the sampling strategy and sampling regions for Germany, France, and Cyprus appear in previous studies (see Koulovatianos et al. (2005, 2007)). The sampling region in China was the urban area of Hangzhou and several towns in the province of Zhejiang. In India the sample was collected from cities and villages of three states of south India, Tamil Nadu, Andhra Pradesh, and Karnataka. The cities where our respondents were surveyed are Chennai (Madras) in Tamil Nadu, Hyderabad (Andhra Pradesh), and Bangalore in Karnataka. The questionnaire was provided in the languages of Tamil (Tamil Nadu), Telegu (Andhra Pradesh), in the English language (respondents from Karnataka preferred English instead of our questionnaires provided in the language Kannada) and elderly respondents were given the option of a questionnaire in Hindi. In Botswana sampling was from the capital Gaborone and villages around it. Apart from questionnaires provided in English, a large part of the respondents were interviewed orally, mainly in the languages Setswana and Kalanga. Sample surveys typically lasted between 20-35 minutes, as respondents had to evaluate 5 different RIs.

3. Appendix C – How NLSE suppresses noise from Heterogeneity in Respondent Perceptions of Verbal Characterizations

The existence of a common, "cardinal" perception of verbal characterizations such as "good" or "bad" is not guaranteed.[3] This problem can make stated Likert-scale values in Part B noisy across individuals. We have named the source of such noise *Heterogeneity in Respondent Perceptions of Verbal Characterizations (HRPVC)*. To suppress such inter-respondent noise we construct the variable "normalized Likert-scale evaluation" (NLSE).

Table C1 presents the descriptive statistics of Likert-scale values stated in Part B for all household types and RIs. The means and medians across household types for a given reference income are close to each other. This lends support to the results of the pilot survey that was run in advance to define the EIs that were provided in Part B:[4] respondents of the present survey also perceive the average incomes stated by the respondents of the pilot survey as EIs.

Figure C1 depicts information from the first column of Table C1, which refers to the one-member household. Each box in Figure C1 is defined by the value of the first and third quartile, so each box contains 50% of the values around the median. A dash within a box represents the median response, while each vertical line spans the range of responses. Except for RI = EUR 2,750, the range of responses covers the whole Likert-scale interval that was provided (from 1 to 100). In particular, for the distribution of responses corresponding to RI = EUR 1,250, both the mean and the median lie in the middle of the range, and the two middle quartiles are distanced symmetrically from the median by 20 points in the Likert scale. So, while Figure C1 shows that there is positive correlation between income and

---

[3] See Kahneman and Krueger (2006, pp. 18-21) for a thorough discussion of this difficulty of inter-respondent comparisons of verbal characterizations of well-being.

[4] These numbers are taken from Koulovatianos et al. (2005) for Germany.

subjective perceptions of living standards, the noisiness of the Likert-scale values indicates the presence of HRPVC. Such noisiness justifies concerns about the effectiveness of using 'raw' Likert-scale values for interpersonal comparisons and about their role as conditioning variables in regressions.

The descriptive statistics of NLSE are given by Table C2 and Figures C2 to C6. By the definition of NLSE, noise stemming from HRPVC should be suppressed. Table C2 confirms this suppressive effect of the NLSE.

4. Appendix D – Calibration of the Representative Consumer in Germany in year 2003

In order to calibrate subsistence consumption so as to replicate the numbers appearing in the utility function given by (19) in the paper, we combine equation (16) in the paper with equation (61) appearing in the paper's Appendix, in order to obtain

$$\beta_j = \psi_{i,j} \cdot \beta_i - \alpha \cdot \chi_{i,j} \ . \tag{D.1}$$

Setting $i = OMH$, where "OMH" denotes a one-member household, and aggregating across all household types, equation (D.1) implies,

$$\sum_{j \in \mathcal{I}} \mu_j \beta_j = \beta_{OMH} \cdot \sum_{j \in \mathcal{I}} \mu_j \psi_{OMH,j} - \alpha \cdot \sum_{j \in \mathcal{I}} \mu_j \chi_{OMH,j} \ , \tag{D.2}$$

where μ_j is the fraction of households belonging to household type $j \in \mathcal{I}$, in order to obtain the term $\beta^{RC}(t)$ given by equation (13) in the text for year 2003. Data for the vector $\{\mu_j\}_{j \in \mathcal{I}}$ in equation (D.2) is taken from Table A3 of Appendix A, which are taken from the German Income and Expenditure Survey in year 2003. Estimates for the vectors $\{\psi_{OMH,j}\}_{j \in \mathcal{I}}$ and $\{\chi_{OMH,j}\}_{j \in \mathcal{I}}$ are taken from the relevant estimated coefficients in Table 1 of the paper, while $\psi_{OMH,OMH} = 1$, and $\chi_{OMH,OMH} = 0$. Since the estimation appearing in Table 1 of

the paper refers to monthly data, we have multiplied the resulting expression for $\Sigma_{j \in \mathcal{I}} \mu_j \beta_j$ from equation (D.2) by 12, in order to obtain the utility function referring to one year.

In aggregative models that use the utility function given by (19) in the paper, the appropriate measure of aggregate income to use is one-member-household equivalent income. A distribution of one-member household equivalent incomes (DOMHEI) transforms household-income data referring to different household types into comparable incomes of identical (one-member) households. Because these one-member-household EIs retain the original level of material comfort of each *individual*, they reflect the inequality of living standards among *individuals* in a country.

The construction of a DOMHEI follows this procedure: consider the household income, y^h, of a household which is household type h with n^h members; based on the estimated values of coefficients a^h and b^h in equation (18) in the paper, find the RI that corresponds to y^h, denoted as y_{RI}^h; assign y_{RI}^h to each household member of that household and include n^h times the income level y_{RI}^h in the DOMHEI. The idea behind the construction of the DOMHEI is to pick each household member from all household types and place him/her into a one-member household (also treating children as adults), providing each individual with the same level of material comfort in this (new) virtual household type as before. The income level y_{RI}^h plays this role of making material-comfort levels equal when transforming all household types into one-member households.

In our application appearing in Figure D1 we have imposed an upper bound on equivalence scales (ESs), equal to the number of household members. This constraint applies when observed household incomes are exceptionally low. Table D1 presents the average ESs based on estimates from Table 1 in the text, imputed in the income distribution for each household type taken from the German Income and Expenditure Survey in year 2003. The expert-based

OECD-modified ESs are presented in the second column of Table D1.[5] It is evident that our average ESs and these of the OECD differ only slightly, justifying the comparison of the two estimates of the DOMHEI appearing in Figure D1. The fact that our ESs fall with RI, shifts poorer (richer) multi-member households to lower (higher) one-member-household EIs, thickening the resulting density. This thickening impacts inequality of one-member-household EIs substantially: the Gini coefficient increases from 27.37% (OECD ES) to 30.54% with our ESs.

Appendix E

Survey Instrument Documentation

Information on the connection between a household's demographic composition and the level of material comfort that its income can buy for its members is important for researchers in diverse disciplines. This survey instrument is designed so as to obtain direct estimates of this connection from respondents.

The survey was implemented in automated and electronic form by a professional research institute, FORSA ("Gesellschaft für Sozialforschung und statistische Analysen mbH" – Research Institute for Social Research and Statistical Analyses). Each participating household was equipped with a "set-top-box" that provided Internet access and that was linked to the household's television set.

An introduction addressed to respondents provides a short explanation of the survey topic and a clarification of the concepts that follow. The actual questionnaire consists of two Parts, Part A and Part B. Part A contains the main evaluation task: to provide incomes that equalize the level of material comfort across different hypothetical household types. Part B poses the same assessment problem as in Part A, but using a different means of communication. Respondents are asked to assess the material comfort of different hypothetical household types with specific income levels on Likert scales.

Key advantages of the survey instrument:
- Direct assessments of incomes that equalize the level of material comfort of different household types, enabling the quantification of household-size economies.
- Posing the same evaluation problem using different means of communication in Parts A and B allows for a test of the effectiveness of the survey instrument, suggested in Part A.
- Relevance of the main evaluation task with observable characteristics of the respondent enables a test of effectiveness of the survey instrument. The socio-economic and demographic composition of the respondent's household, may limit her/his available information and ability to evaluate hypothetical household types and levels of material comfort, thus contaminating the results due to a limited-information bias. Comparing answers from respondents whose socio-economic and demographic characteristics are close to those of the hypothetical households they examine with answers from all other respondents enables a test for limited-information bias.
- Low respondent burden: respondents can complete the questionnaire (Introduction, Parts A and B) in about 10-25 minutes.
- High flexibility: Parts A and B can be adjusted easily so as to encompass other hypothetical household types and levels of material comfort.

Introduction for the respondents

Purpose of the survey
In general, different household types may need different incomes in order to attain the same level of material comfort. Since assessing such incomes in an objective way is difficult, we would like to ask you for your personal evaluation of these incomes for a number of different household types. Please note that in this questionnaire there are no "right" or "wrong" answers. So, your answers should only reflect your personal judgements.

[Technical note to the researcher. Respondents click a button to switch to the next screen.]

Instruction
You will frequently read the expression "monthly net household income." Such a "monthly net household income" is the income amount a household has at its disposal after paying taxes and social security contributions (health insurance contributions, compulsory long term care insurance contributions, unemployment insurance contributions, and contributions to the pension system).

"Monthly net household income" encompasses:
Salary and earnings,
Income from being self-employed,
Pensions,
Unemployment benefits and social benefits,
Accommodation allowance,
Child allowances,
Incomes from rent and lease, and
Other incomes such as returns on investment, interest, etc.

[Technical note to the researcher. Respondents click a button to go to the next screen.]

PART A

Now, please think about a situation where a single, childless adult has a monthly net household income of 500 Euros.

In this survey, there are seven other household types:
with 1 adult and 1 child
with 1 adult and 2 children
with 1 adult and 3 children
with 2 adults and no children
with 2 adults and 1 child
with 2 adults and 2 children
with 2 adults and 3 children

Assume that adults are ages 35 to 55 and children are ages 7 to 11.

[Technical note to the researcher. Respondents click a button to go to the next screen.]

Which monthly net household income would each of these seven household types need in order to attain the same level of material comfort as the single, childless, adult household with the monthly net household income of 500 Euros?

You should state this monthly net household income for each household type in the table that will follow on the next screen. Please note that your answers should reflect only your personal judgements.

[Technical note to the researcher. Respondents click a button to go to the next screen.]

Which monthly net household income would each household type need in order to attain the same level of material comfort as the single, childless, adult household with the monthly net household income of 500 Euros?

Please state income amounts in Euros.

1 adult without children	500 Euros
1 adult, 1 child	
1 adult, 2 children	
1 adult, 3 children	
2 adults, no children	
2 adults, 1 child	
2 adults, 2 children	
2 adults, 3 children	

[Technical note to the researcher. The reference income level provided in the table is randomly assigned to the respondents. If a respondent does not report an income amount for a household type, there is a reminder: "please fill in income amounts in all empty cells of the table." If a respondent's entries are not numbers, there is a reminder: "please state numbers only." If a respondent states income amounts that are decreasing inversely with household size, a box opens: "Usually, larger household types also need higher incomes in order to attain a specific living standard. Please, make sure that you are not stating how much income should be added compared to a smaller household type, but how much the total net household income should be. Please make sure that the entries you made are indeed total net household incomes." This box opens only once, and its intention is to reduce misunderstandings by respondents. However, if a respondent did not adjust the entries she/he made in the table, she/he was free to do so. Respondents click a button to go to the next screen.]

PART B

We will show you several household types with a given monthly net household income. Please evaluate the material comfort that these monthly net household incomes bring to the different household types on a scale ranging from 1 to 100 points. The values of this scale have the following meaning:

Level of material comfort

Please complete the following table by evaluating the monthly net income of each household type on the scale of 1-100.

All values between 1 and 100 are permissible.

	Level of material comfort (in points)
1 adult, no children with 3,500 Euros	
1 adult, 1 child with 3,900 Euros	
1 adult, 2 children with 4,200 Euros	
1 adult, 3 children with 4,550 Euros	
2 adults, no children with 4,850 Euros	
2 adults, 1 child with 5,250 Euros	
2 adults, 2 children with 5,550 Euros	
2 adults, 3 children with 5,850 Euros	

[Technical note to the researcher. The numbers provided in this table are estimates of average equivalent incomes for five reference income levels from an independent study. The five reference incomes are the same as the reference income levels in Part A. So, altogether, five profiles of equivalent incomes (including a reference income for the single, childless, adult household) were evaluated by the survey sample, one profile per respondent. One out of these five equivalent-income profiles was randomly assigned to a respondent. If a respondent reports less than eight Likert scale values, there is a reminder: "please fill in all empty cells of the table." If a respondent's answers do not fall in the given range of the Likert scale (1-100), there is a reminder to "please state numbers between 1 and 100 only."]

Tables for Appendices A - D

Table A1. Distribution of household types in Germany. Data refer to the overall population and are taken from the German Income and Expenditure Survey in 2003.

	Household type								
	1 adult, 0 children	1 adult, 1 child	1 adult, 2 children	1 adult, 3 children	2 adults, 0 children	2 adults, 1 child	2 adults, 2 children	2 adults, 3 children	Other
Number of households (in thousands)	14,031.1	931.4	356.3	45.4	11,208.4	2,440.9	2,963.2	808.3	5,312.8
% of population	36.83	2.44	0.94	0.12	29.42	6.41	7.78	2.12	13.95

Table A2. Description of the personal characteristics of the 2,042 respondents in the survey. [a] Respondents who have completed schooling sufficient for general qualification for entrance to a German University; [b] Respondents who stated that they have an occupation, and they either did not state their occupation type, or their occupation type did not fit in the other working categories; [c] Respondents who stated that they are non-working, and they either did not state their status, or their status did not fit in the other categories.

		Number of respondents	% of respondents
Region	Former West Germany	1,541	75.5
	Former East Germany	501	24.5
Gender	Male	465	22.8
	Female	1,577	77.2
Education	No degree	42	2.1
	Basic level of schooling (9 years)	587	28.7
	Secondary School	926	45.3
	Advanced technical college	119	5.8
	High School [a]	163	8.0
	Completed technical school or university	205	10.0
Occupational Status	Self employed	43	2.1
	Civil servant	57	2.8
	White collar	583	28.6
	Blue collar	180	8.8
	Pupil, student, trainee	23	1.1
	Working, other [b]	52	2.5
Status of non-working	Pensioner	327	16.0
	Unemployed	152	7.4
	Housewife/man	452	22.1
	Obligatory military / public service	101	4.9
	Non-working, other [c]	72	3.5
Family after-tax income class	Less than 500 EUR	36	1.8
	Between 500 and 1000 Euros	239	11.7
	Between 1,000 and 1,500 Euros	385	18.9
	Between 1,500 and 2,000 Euros	437	21.4
	Between 2,000 and 2500 Euros	382	18.7
	Between 2,500 and 3,000 Euros	242	11.9
	Between 3,000 and 3,500 Euros	159	7.8
	Between 3,500 and 4,000 Euros	68	3.3
	Between 4,000 and 4,500 Euros	44	2.2
	4,500 Euros or more	50	2.4
Age group	Between 18 and 40 years	863	42.3
	Between 40 and 60 years	831	40.7
	60 years or older	348	17.0
Partner in the household	Yes	1,396	68.4
	No	646	31.6
Number of children in the household	0	860	42.1
	1	521	25.5
	2	491	24.0
	3 or more	170	8.3

Table A3. Distribution of household types of respondents in the survey sample (first two rows). The last row refers to the overall German population, using data from the most recent German Income and Expenditure Survey in 2003. Numbers appearing in the third row are percentages of the sum of households belonging to the eight household types presented in this table.

|	Household type							
	1 adult, 0 children	1 adult, 1 child	1 adult, 2 children	1 adult, 3 children	2 adults, 0 children	2 adults, 1 child	2 adults, 2 children	2 adults, 3 children
Number of respondents	445	125	57	19	415	396	434	151
% of respondents	21.79	6.12	2.79	0.93	20.32	19.39	21.25	7.39
% of population in 2003	42.80	2.84	1.09	0.14	34.19	7.45	9.04	2.47

Table A4. Distribution of respondents having an adjusted disposable household income that is similar to the reference income they were asked to evaluate in Part A of the questionnaire. The adjusted disposable household income is the disposable household income divided by the estimated equivalence scale for the respondent's household type. The estimated equivalence scale is the average equivalence scale from responses to Part A.

Respondent's household type	Number of respondents	Percentage of overall sample	Percentage of all respondents who belong to the same household type
1 adult, 0 children	88	4.31	19.78
1 adult, 1 child	26	1.27	20.80
1 adult, 2 children	15	0.73	26.32
1 adult, 3 children	5	0.24	26.32
2 adults, no children	77	3.78	18.55
2 adults, 1 child	77	3.78	19.44
2 adults, 2 children	93	4.55	21.43
2 adults, 3 children	34	1.67	22.52

Table B1a. Breakdown of the samples in Germany, Cyprus, and France

		Germany Sample: 167 obs.		Cyprus Sample: 130 obs.		France Sample: 223 obs.	
		N	%	N	%	N	%

Table D1. Average equivalence scales. Equivalence scale estimates taken from the regression in Table 1 in the text depend on the level of material comfort. These equivalence scale estimates are used in order to construct a distribution of one-member households' equivalent incomes from the (most recent) German Income and Expenditure Survey in year 2003. The averages of the equivalence scales imputed in the German Income and Expenditure Survey income distribution (for each household type) are reported in the first column of this table.

Household type	Average equivalence scales from the estimates of the present study	OECD-modified equivalence scale
1 adult, 1 child	1.32	1.30
1 adult, 2 children	1.55	1.60
1 adult, 3 children	1.83	1.90
2 adults, 0 children	1.64	1.50
2 adults, 1child	1.83	1.80
2 adults, 2 children	2.04	2.10
2 adults, 3 children	2.29	2.40

Figures for Appendices C and D

**Figure C1**. Box plots of stated Likert-scale values for the reference household.

Figure C2. Box plots of Normalized Likert-scale Evaluations for different household types at a reference income of 500 Euros.
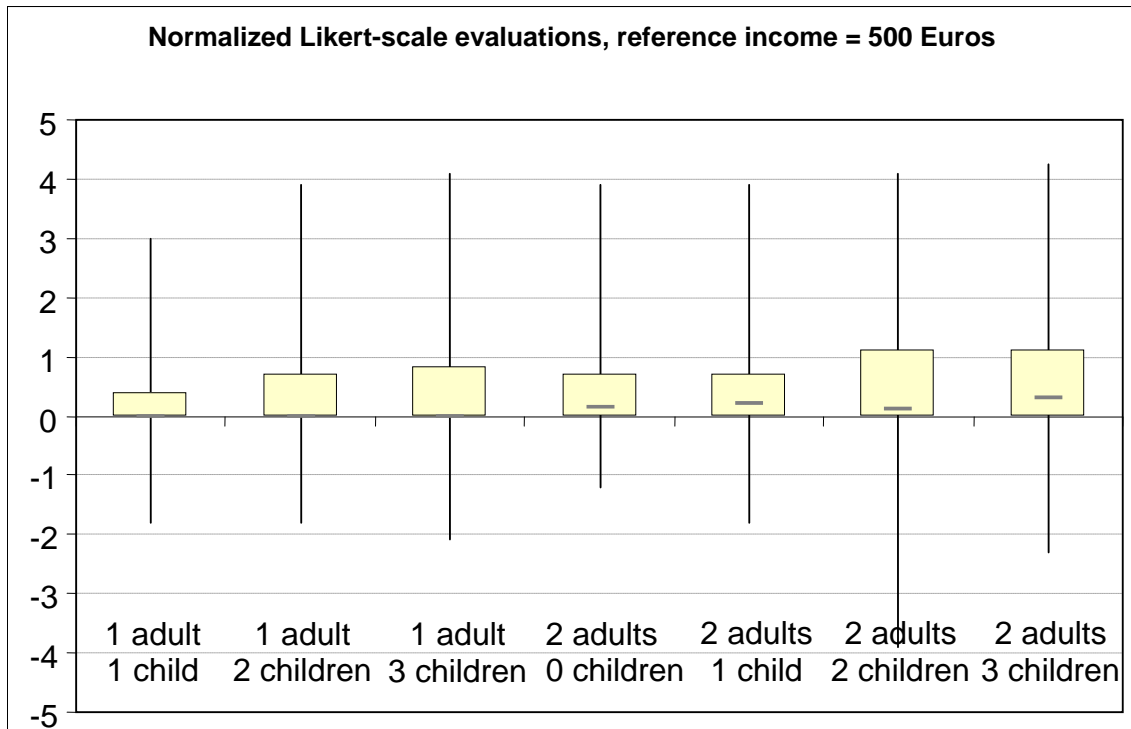

Figure C3. Box plots of Normalized Likert-scale Evaluations for different household types at a reference income of 1,250 Euros.

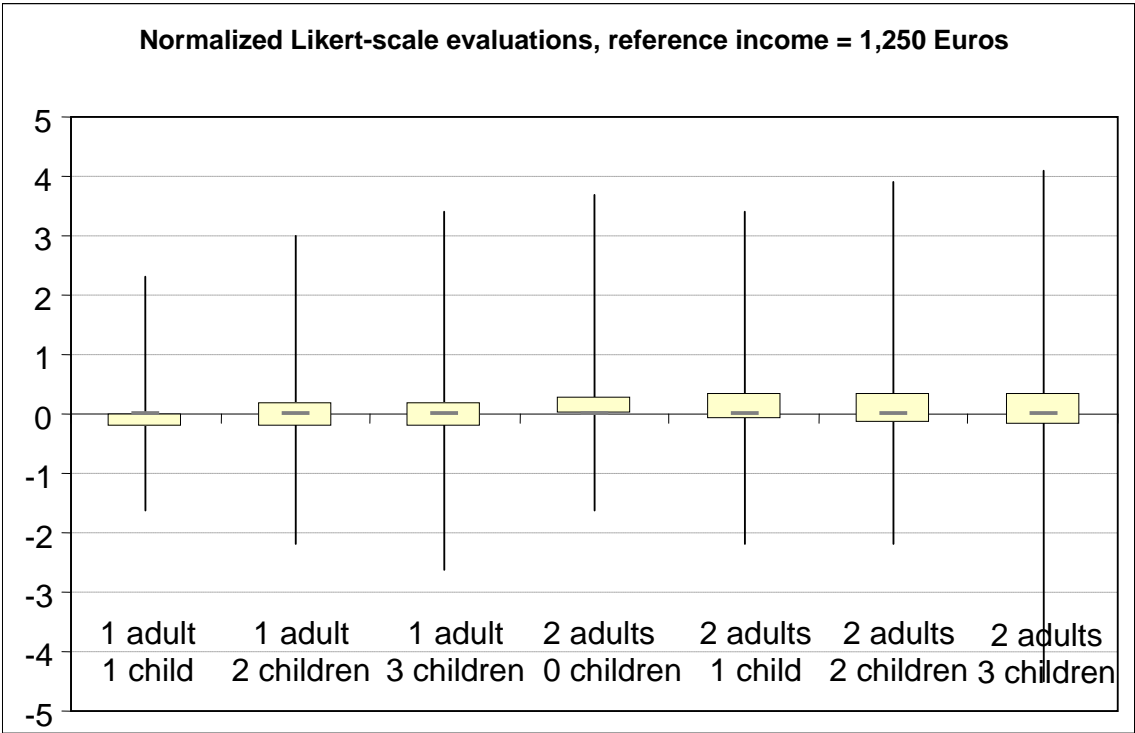

Normalized Likert-scale evaluations, reference income = 1,250 Euros

Figure C4. Box plots of Normalized Likert-scale Evaluations for different household types at a reference income of 2,000 Euros.

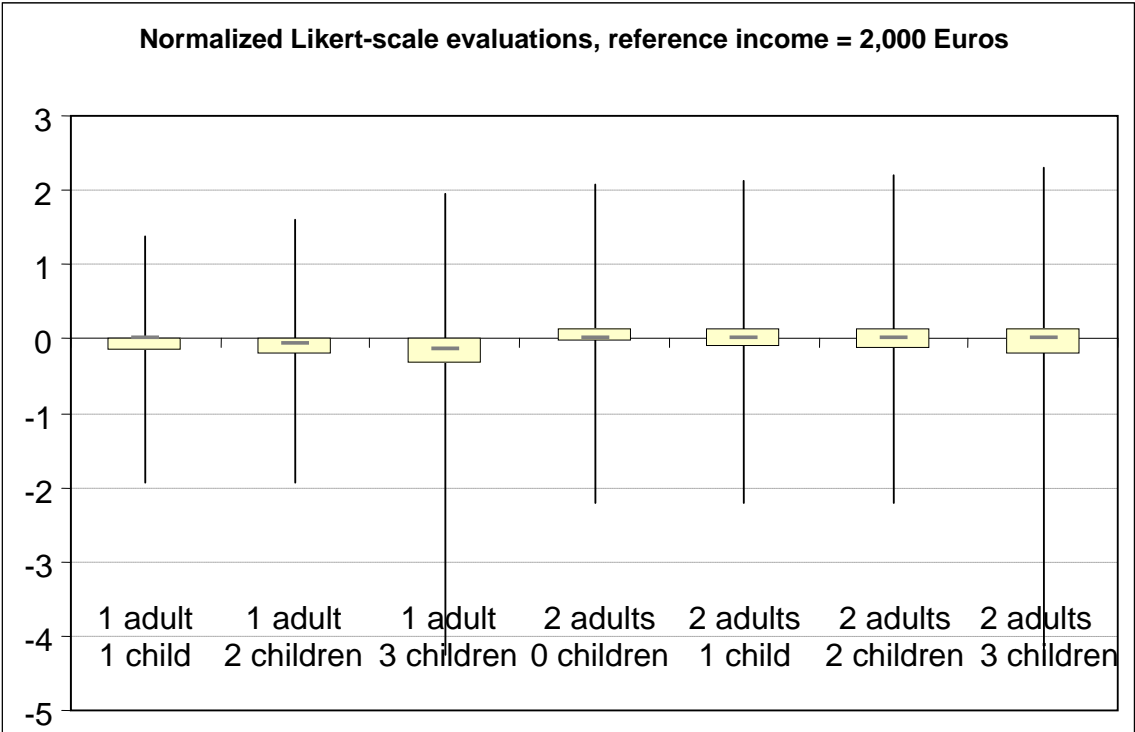

Normalized Likert-scale evaluations, reference income = 2,000 Euros

Figure C5. Box plots of Normalized Likert-scale Evaluations for different household types at a reference income of 2,750 Euros.

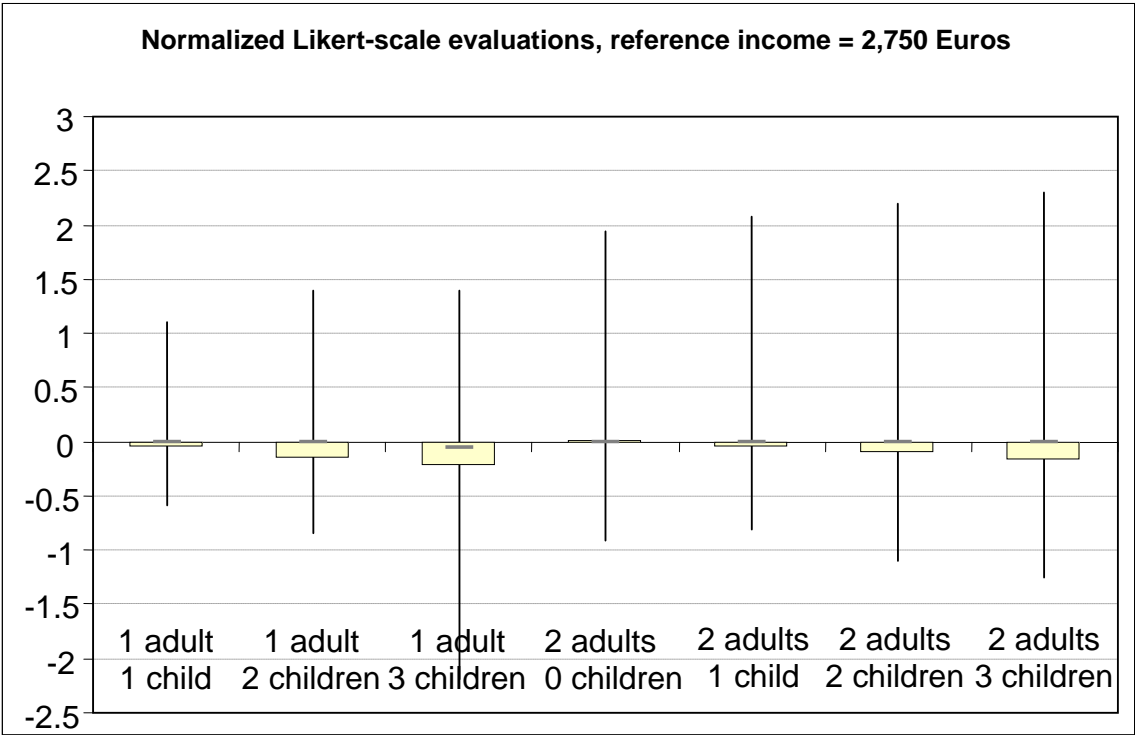

Figure C6. Box plots of Normalized Likert-scale Evaluations for different household types at a reference income of 3,500 Euros.
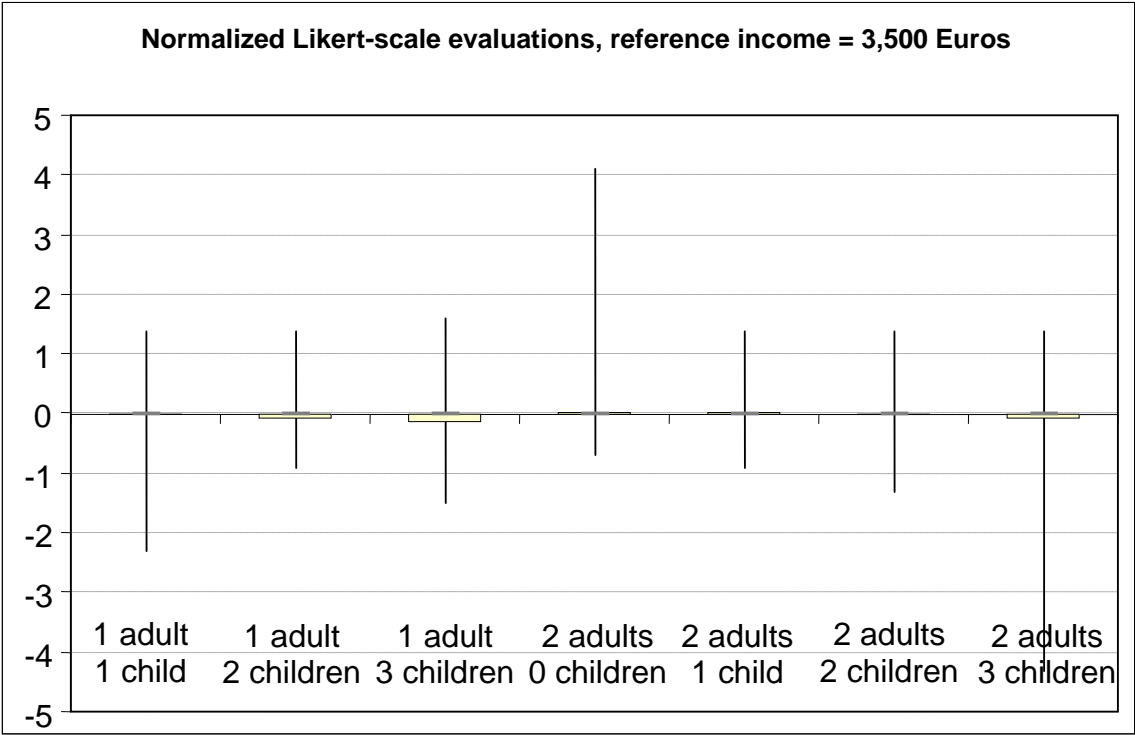

Figure D1. Distribution of one-member-household equivalent incomes calculated using the OECD-modified equivalence scales and equivalence-scale estimates taken from the regressions in Table 1 from the present survey. Household-income data are taken from the German Income and Expenditure Survey 2003.
